20. ABSTRACT (Continue on reverse side if necessary and identify by block number) The involute lay-up technique has been utilized for fabrication of ablative and carbon/carbon nozzle components for approximately fifteen years. However, the thermal and structural analyses have always been plagued by the lack of data and, more important, a need for a predictive model. Almost every component designed has a different helix or arc angle and little, if any,

data existed for each ~~new~~ involute configuration. A model for predicting stress/strain behavior in the cylindrical form using flat laminate mechanical properties was developed by the Air Force Materials Laboratory. The test program conducted to verify this model, using empirical results has been completed. Both a graphite reinforced epoxy and a basic two dimensional carbon/carbon were tested with variables of arc and helix angles. Based on the laminate properties which were obtained during the test program, predictions were made for three graphite/epoxy cylinders and fifteen carbon/carbon cylinders with both uniaxial and combined loading. The cylinders were tested to failure in axial tension, axial compression, hoop tension, hoop compression, and clockwise and counterclockwise torsion. The overall predicted strain measurements were in good agreement with the predicted behavior. As expected, the modeling of the inelastic behavior of the carbon/carbon materials requires some modifications and interaction to improve the predicted behavior at loads greater than fifty percent of ultimate strength. However, the model has been demonstrated to be a useful tool, and it will be used to predict behavior as new materials and varying arc and helix angles are used in the fabrication of nozzle components.

FOREWORD

The work described in this final report was performed under Contract F33615-77-C-5051 by the Strategic Systems Division of the Aerojet Solid Propulsion Company under the technical direction of Dr. N. J. Pagano (AFML/MBM).

This program can be considered as a part of the continuing efforts by the Air Force Materials Laboratory to understand and predict the behavior of C-C involute structures used for rocket nozzle exit cones.

H. O. Davis was the Principal Investigator for this effort. D. F. Vroney, with the support of Dr. N. J. Pagano, AFML, conducted the analytical studies. The author gratefully acknowledges the contributions of:

R. D. Steele - Testing
K. M. Schalinski - Tool Design
and
George Lucido - Kaiser Aerotech - Fabrication of test articles

The work was initiated in September, 1977, and completed in June, 1979.

SECTION I

INTRODUCTION

The primary fabrication technique used for cylindrical components, and more specifically exit cones for solid rocket motors, requiring a carbon/carbon material has been the involute layered concept. The involute technique has evolved as a means of positioning layers of material providing a continuous ply orientation from the inside to the outside diameter and from top to bottom. This provides a free standing structural component without overwrap or contained structural backup. Furthermore, with the inherent high temperature capabilities of carbon/carbon materials, the structure functions without insulation except as needed to protect other nozzle and/or chamber components. Alternatives have been evaluated and in some instances tested in rocket motor firings but a fabrication technique to replace the involute concept has not been demonstrated to date. However, failures of composites made by the involute ply orientation during fabrication and also test firings has emphasized the need for better analysis tools. An analysis technique and computer code were developed by the Air Force Materials Laboratory, Reference 1. The program utilizes laminate properties to predict strain and deformation of cylinders fabricated in any involute configuration.

The plies of material in a cylindrical or conical involute section cannot be oriented exactly as a layered laminate. Furthermore, the cylinder or cone with changing axial and cylindrical characteristics in the involute or spiral lay-up orientation presents a difficult problem for prediction of cylinder or cone behavior. The AFML program provides a resolution of the problem for involute cylinders. Selected involute configurations were identified for validation of the computer model in a program started in September 1977 and completed in June 1979.

Reference 1: Pagano, N.J., "Elastic Response of Rosette Cylinders Under Axi-symmetric Loading" AIAA Journal, Vol. 15, No. 2, Feb. 1977 pp. 159-166

The purpose of this test and analysis program was to verify the capabilities of AFML's computer program to use laminate elastic constants to predict the strain and deformation of involute cylindrical structures when subjected to a variety of individual and combined loading conditions. In addition, the program provides a more comprehensive data base for layered two dimensional (2D) carbon/carbon composites through the testing of laminates, thin wall tubes, and involute cylinders.

The program steps and scope and sequence of major tasks are shown in Figure 1.

Figure 2 describes the involute ply configuration and identifies the terminology used in this report. Two ply patterns are also shown. The ply pattern on the left has a 0 degree helix angle and the one on the right has a 45 degree helix angle.

The objectives of this report are (1) to present the mechanical, physical, and thermal measurements for a graphite unidirectional fabric in an epoxy matrix and bidirectional graphite fabric in a carbonaceous matrix; (2) to compare predicted and measured strains of cylinders in the z and θ planes and 45 degree to the z plane and, (3) to evaluate the effects of non-linear elastic constants on the capability of the program.

Also included in this report are:

1. Descriptions of materials.
2. Processing histories for graphite/epoxy and carbon/carbon materials.
3. Test specimen configurations.
4. Test procedures.
5. Compilation of results.
6. Comparisons of predicted vs measured strain.
7. Evaluations of cylindrical failure mode in relation to measured ultimate strengths.

SECTION II

SUMMARY

The initial portion of the test program consisted of tension, compression, torsion, and shear testing of graphite/epoxy and resin/pitch WCA fabric reinforced carbon/carbon laminates and thin wall tubes. The carbon/carbon material tested was fabricated by Kaiser Aerotech and is identified as K-Karb 1200. Ultimate strengths in compression, tension, and shear were obtained as well as elastic constants for tension and compression moduli, Poissons ratios, and shear moduli relative to the axes of material symmetry.

The laminate properties shown in Figure 3 were measured and used to predict strain and deformation of cylinders fabricated by the involute process. The tension and compression results from the carbon/carbon laminates are summarized in Table I. The results were in agreement with previous tests of the same material. Density variation for the laminates was less than ± 0.01 grams/cc, indicating a uniform material.

Cylinders were fabricated from both materials using three combinations of involute parameters: 10 degree arc 0 degree helix, 5 degree arc 45 degree helix, and 10 degree arc 45 degree helix. Strain gages were bonded to each cylinder in three equally spaced locations. Axial, circumferential, and 45 degree to warp strain measurements were made for uniaxial and combined loading.

The predicted linear strain behavior for both the graphite/epoxy and carbon/carbon materials produced good agreement with measured results. After the carbon/carbon material became nonlinear at about 75 percent of ultimate strength, the measured strain was significantly greater than predicted. Additional modeling is required using the elastic properties at 75 to 100 percent of ultimate strengths. One nonlinear model for carbon/carbon was demonstrated on one set of 45 degree helix cylinder compression results with good agreement.

SECTION III

TECHNICAL DISCUSSION

The technical discussion is arranged in the same sequence as used to conduct the program. The program was initiated by selecting materials and concluded by comparing predicted versus measured strains. The predictions for uniaxial and combined loading were made prior to testing the cylinders. Laminate testing for the graphite/epoxy and carbon/carbon material was completed prior to initiation of cylinder testing. The selection of a control material was justified in that the test specimens configurations and test procedures were verified prior to testing the primary material, a standard 2D carbon/carbon. Furthermore, the graphite/epoxy exhibited linear behavior to failure, and the carbon/carbon was only linear to approximately 75 percent of ultimate strengths.

The test procedures were based on proven techniques using ASTM standards or other approved methods. The testing to failure of the thin wall cylinders proved not to be satisfactory and produced lower ultimate strengths than the comparable laminate test; however, the elastic constants were equivalent.

The discussion is divided into the following major sections: material selection, processing of laminates and cylinders, mechanical, physical and thermal properties of laminates and thin wall cylinders, testing of cylinders and prediction of cylinder behavior and correlation with measured data.

The laminate and tube test matrix is shown in Figure 4. Rail shear tests, Reference 2, were also measured on graphite/epoxy and carbon/carbon material. Duplicate testing is shown; however, in some cases for compression and tensile moduli, nine test values were obtained. Three values for ultimate strengths were obtained with few exceptions.

Three variations of arc and helix angles of the involute configuration were tested. The complete matrix is shown in Figure 5.

A. MATERIALS SELECTION

Two materials were required to conduct the evaluation of the computer program. Although the program was directed primarily toward carbon/carbon materials, a material which could be readily fabricated with lower cost and more ideal behavior was needed as a control material. A graphite/epoxy material which had a high anisotropy, warp to fill, was selected as the composite material to verify the capability of the computer program to predict elastic response. The material selected is a 4 to 1, warp to fill ratio, fabric containing T-300 1000 filament yarn, a product of Union Carbide. The fabric was woven and impregnated by Fiberite Corporation, Winona, Minn. The material was designated ASPC 3431/934. The woven fabric had been previously evaluated and was chosen for the epoxy system because of its excellent mechanical properties with phenolics.

The certification data for the lot of material used is presented below:

Certification Data for ASPC-3431/34

Date of Manufacture	11-7-77

Cured Ply thickness, in.	0.0062

These data were obtained prior to initiation of fabrication of laminates or cylinders.

The carbon/carbon material was selected based on its wide usage in current high performance solid rocket nozzles, plus the considerable amount of existing data for both laminate and involute structures. The reinforcement is the fabric normally used in low modulus intermediate density two dimensional (2D) carbon/carbon structures. The fabric was impregnated by Fiberite Corporation to make their standard Karbon 408 graphite/phenolic material system. The description of the material and the certification properties of the material used are shown below:

Certification Data for K408

Date of Manufacture	11-2-77
Lot Number	A8-042
Resin Solids, %	32.6
Volatile Content, %	3.0
Filler	Not Reported
Laminate Flow, % (100 psi)	14.8
Short Beam Shear (Warp) psi	3140
Dowel Shear, psi	2870
Flexure Strength (Warp) psi	30590
Flexure Mod (Warp) psi $\times 10^{-6}$	1.9
Fabric	WCA

Weave	Square (Plain)
Thread Count, Yarns/Inch	
Warp	27
Fill	21
Filaments/Yarn Bundle	1440

Other suppliers of these types of materials are available within the industry. Some fabricators use alternate and interchangeable sources of resin for making the low modulus carbon/carbon composites; the reinforcement is generally WCA. The interchangeability of sources is desirable; however, the only accepted approvals for verification as to equivalency is structural, thermal, and erosive behavior in the use environment.

B. PROCESSING OF LAMINATES, TUBES, AND CYLINDERS

The size and number of laminates, tubes, and cylindrical billets was determined based on the requirements of the test matrices shown in Figures 4 and 5. The total test materials consisted of:

<u>MATERIAL</u>				
	<u>Graphite/Epoxy</u>		<u>Carbon/Carbon</u>	
	<u>No.</u>	<u>Size, in.</u>	<u>No.</u>	<u>Size, in.</u>
Laminates	2	12 by 12 by 0.25	2	12 by 12 by 0.25
	2	6 by 3 by 3	2	6 by 3 by 3
Tubes	6	6 long by 2.008 ID and 2.126 OD	9	6 long by 2.008 ID and 2.126 OD
Involute Cylinders	3	8 long by 4.016 ID and 4.803 OD	15	8 long by 4.016 ID and 4.803 OD

1. Graphite/Epoxy

The graphite/epoxy laminates and cylinders were processed by Kaiser Aerotech, San Leandro, California. The cure pressure was 100, +5,-0

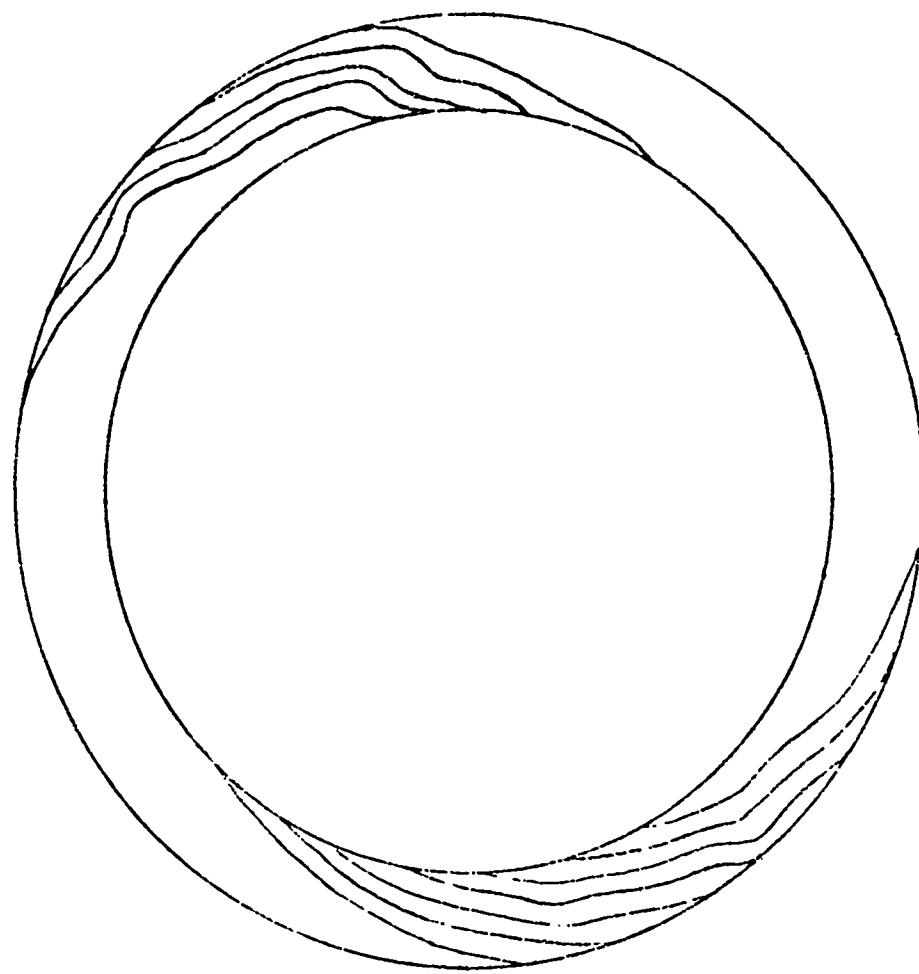

psi, and the final cure phase was for 120, +15, -0 minutes hold at 350, +10, -0°F. The heating rate was 2 to 3°F per minute with a step hold at 250°F for 65, +5, -0 minutes. The laminates, tubes, and cylinders were processed by the same cycle. However, the first attempt to fabricate cylinders from the high flow angle material produced wrinkles in the ply arc angle as shown in Figure 6. The material was not sufficiently stiff in the fill direction to prevent wrinkling. The cylinders were refabricated by staging the material at 180°F for 20 minutes prior to cutting plies and laying-up in the female mandrel. The staging produced a more rigid ply which slipped at the ply interface rather than binding and wrinkling. Ply spacing lines were also placed on the mandrel in order to better control the ply location. The plies were debulked as a unit. It was not necessary to allow for shrinkage; however, the cylinders were made about 0.250 in. excess in the cylinder wall and machined to final configuration.

There was no other difficulty encountered in making the laminates, tubes, and cylinders.

The radiographic and visual inspection indicated satisfactory laminates, tubes, and cylinders by the processes utilized. Further discussion of quality is contained in the test data section. The critical control parameters were verification of the following.

- a. Material type and lot number.
- b. Ply shape and warp/fill direction.
- c. Number of plies.
- d. Staging of material.
- e. Vacuum 24 in. Hg
- f. Cure/pressure cycle.
- g. Finish dimensions.
- h. No delaminations or wrinkles.

The number of plies, ply width, and arc angle (average shown) for each of the three graphite/epoxy cylinders were verified by using the method described in Reference 1.

**Figure 6. Discrepant Graphite/Epoxy Cylinder
Showing Ply Pattern Wrinkles**

The helix and arc angles for the cylinders were selected to provide a rigorous test of the AFML model, i.e., high arc angles and maximum helix angles. The matrix for the graphite/epoxy is shown in Figure 5.

The number of plies were as follows:

Average Arc Angle, degrees	Helix Angle, degrees	Number Of Plies
5	45	172
10	45	324
10	0	324

The actual and calculated ply width for the 5 degree arc angle cylinder was 7.9 in. for the as-cured billet which was 4.0-in. ID and 5.3-in. OD. The ply width for the 10 degree arc angle was 4.2-in. for the as-cured billet.

2. Carbon/Carbon

The carbon/carbon laminate, tubes, and cylinders were produced by standard carbon/carbon processing. The process for carbon/carbon structures requires many more steps than the graphite/epoxy. However, the initial process of compaction (debulking) and cure are similar. The processing steps for the carbon/carbon are shown in Figure 7.

All of the compacting (debulking) for the laminates, tubes, and cylinders occurred during the cure/pressure cycle. The cure/pressure cycle included a final cure temperature of $310 \pm 10^{\circ}\text{F}$ at a cure pressure of 200 ± 10 psi. Some of the processing steps, including heating and cooling rates, are considered proprietary by the fabricator. The process temperatures and heating rates were approved prior to fabrication. The maximum temperature and minimum time at conversion temperatures are shown as follows:

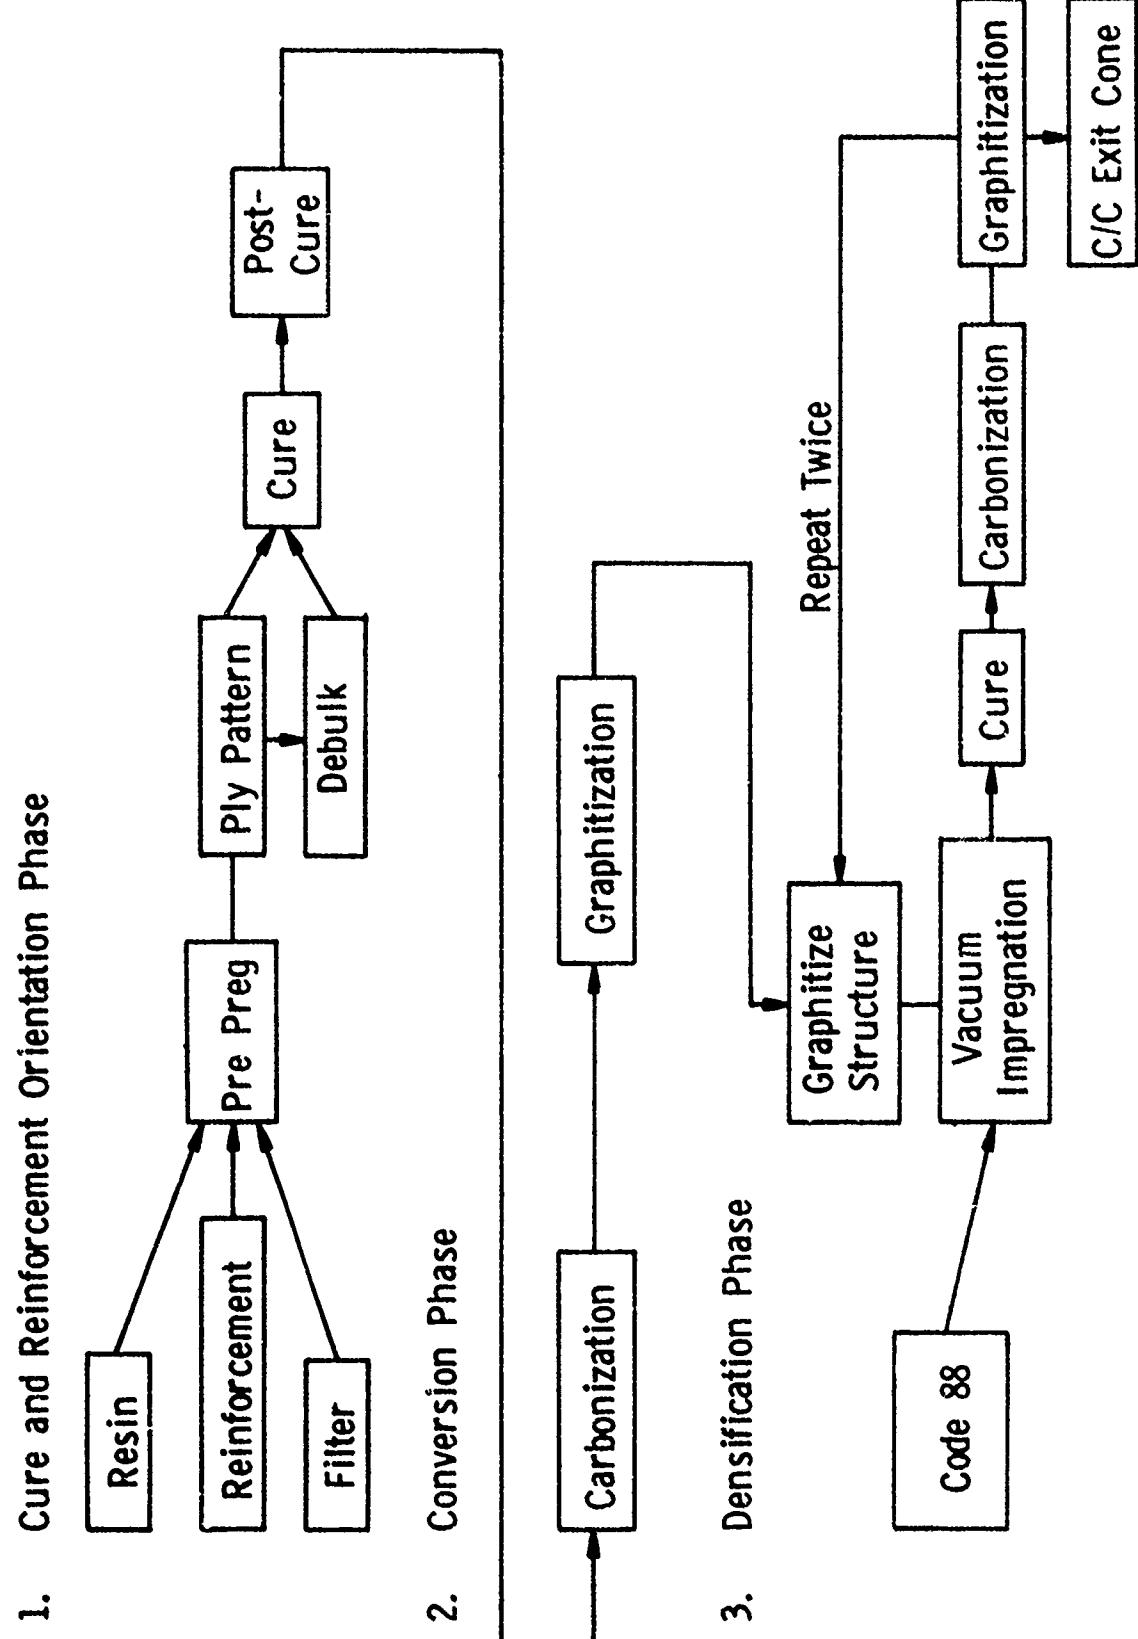

Figure 7. Processing Steps for Production of Carbon/Carbon Material

<u>Process</u>	<u>Maximum Temperature Range °F</u>	<u>Time at Maximum Temperature, hr</u>
Postcure	500 +25, -0	24
Carbonization	1500 +50, -0	4
Graphitization	4500 ± 100	4

The maximum temperature for the conversion process of the Code 88 impregnation also consists of a graphitization cycle at $4500 \pm 100^{\circ}\text{F}$ with a minimum hold of 30 minutes.

All process steps are considered critical to achieving the final required specific gravity of 1.50 minimum. The following major checks and verification were made during the processing of the carbon/carbon laminates, tubes, and cylinders

- a. Material identification and lot number
- b. Ply dimensions and warp/fill orientation
- c. Bagging material and bleeder thickness
- d. Ply pattern location and orientation in mold
- e. Vacuum 24-in. Hg minimum and cure pressure cycle
- f. Removal of surface glaze
- g. Weight and dimensions
- h. No wrinkles after cure - no delaminations after each process step.
- i. Postcure cycle - temperature limits
- j. Carbonization cycle - temperature limits
- k. Graphitization cycle - temperature limits
- l. Impregnation cycle
 - (1) Temperature
 - (2) Pressure
 - (3) Time
- m. Conversion cycles for Code 88
- n. Final density
- o. Final radiograph inspection for delamination

There were anomalies reported for dimensions on the tube specimens. Seven of the nine tubes had to be refabricated. Graphite sleeve rounding fixtures were used in the inside diameter of the tubes and cylinders. The tubes were made from spliced gore patterns to achieve ply orientation parallel to the surface with arc angle 1 degree. The laminates and cylinders were within the specified dimensions.

C. MECHANICAL AND THERMAL PROPERTY MEASUREMENT

1. Mechanical

A structural analysis was conducted on each test specimen configuration using a conventional two dimensional finite element program. Each of the test specimen configurations shown in Appendix A was analyzed during loading. The properties necessary for the prediction of cylinder behavior are shown in Figure 3. Some of the Poisson's ratios and the moduli were measured in tension and compression; however, the computer code does not discriminate between tension and compression data. The additional properties determined are also included in Figure 3. Additions are shown in parentheses. Ultimate strengths were obtained in tension, compression, torsion, and shear. Initial stress strain measurements were made at least once prior to failure for the elastic constants. All compression specimens were partially loaded and unloaded in tension (approximately 50 percent of ultimate load) prior to the partial and ultimate loading in compression. This has added scope to the program to verify moduli from the identical specimen and eliminate the possible effect of non-uniform material. There were no significant differences between results from the tension only specimens and the tension/compression specimens.

The graphite/epoxy and carbon/carbon specimens had the same configuration except for short beam shear testing. The carbon/carbon specimen was 0.4-in. thick and the graphite/epoxy was 0.250-in. thick. Thicknesses were calculated to produce shear failures rather than tension or compression failures in bending for each of the materials.

a. Graphite/Epoxy

A summary of the average graphite/epoxy mechanical property measurements is shown in Table 2. The values are nominal or average values. All mechanical property measurements are shown in Table 3. The values obtained were as expected with the exception of the very good warp properties of the ASPC 3431/34. The ultimate warp tensile strength was 190,000 psi and the ultimate warp compression was 140,000 psi. This compares favorably with unidirectional tape tensile of approximately 200,000 psi. Furthermore, the fabric provides 40,000 psi fill tensile and 70,000 psi fill compressive strength.

Three types of shear tests were conducted. The average values ranged from 5,000 to 14,400 psi in the warp direction and from 3,600 to 7,000 psi in the fill direction. The low value of 7,000 psi (warp) for the rail shear is not consistent with the other results. The test samples are suspect, possible damage before test or during assembly into the rail shear fixture. The samples were radiographically inspected and no discrepancies could be isolated prior to starting specimen assembly. There was not sufficient material for retest as a result of the material usage for making cross ply tensile specimens.

All of the laminate specimens were checked for fiber volume and resin content and void volume. The values obtained are shown below:

<u>Test Panel</u>	<u>Specific Gravity</u>	<u>Resin Solids, %</u>	<u>Fiber Volume, %</u>	<u>Void Content, %</u>
TP 3431-101-1	1.57 ⁽¹⁾	36.9	55.81	-0.376

The calculations for fiber volume and void content were made using 1.76 as the specific gravity of the graphite filament and 1.30 for the resin matrix. The negative void contents are observed quite often for high modulus graphite reinforced laminates. The calculated number is based on a nominal specific gravity. A negative void content is indicative of a low void panel.

A photograph of a tube with end sleeves attached (bonded with epoxy) for torsion and compression testing of the thin wall tubes is shown in Figure 8. Strain gages for axial, hoop and 45 degree measurements are shown bonded in place for test. Three of the tube specimens (configuration shown in Appendix A) were tested in compression. The average value obtained was 85,000 psi, or approximately one half of the laminate test results.

The thin wall tubes, shown in Appendix A, were designed primarily to obtain the G_{12} shear modulus and to have a backup compression test. The tube was satisfactory for obtaining G_{12} but did not produce ultimate compression strengths comparable to the laminate uniaxial test (configuration in Appendix A). The tube data recorded in Table 3 produced warp compression values approximately 40 percent lower than the values produced by dogbone type specimens, 85,000 psi compared to 140,000 psi. Similarly, the tube fill compression values were approximately 20 percent of the values produced by the dogbone specimens, 57,000 psi compared to 73,000. Although the specimens were analyzed and determined to have satisfactory thickness to gage length dimensions, apparently some buckling occurred. Observation of the failure surface after test showed delamination, separation of plies, and a crushed interface.

The torsion specimens with warp in the axial direction produced a fill tensile failure with the failed surface parallel to warp yarns. The test plan scope did not include torsion tests to failure for tube specimens with the fill in the axial direction.

The tensile and compression failures were characteristic of high modulus graphite fabric reinforced epoxy, Reference 3.

An example of the stress/strain curve for a compression and tensile failure of a laminate is shown in Figures 9 and 10. The strain gages were aligned with the warp surface (axial), fill surface (tang.) and cross ply surface. These strain measurements were used to determine ν_{13} and ν_{12} .

An example of the stress/strain curve for determination of G_{12} (tube specimen) is shown in Figure 11.

The variation of the test results was within that normally obtained for graphite fabric reinforced epoxies. However, the variance was not determined for this test program because of the low frequency of tests with the exception of the elastic moduli for tension and compression.

b. Carbon/Carbon

The primary emphasis of the laminate and tube testing phase was directed toward obtaining representative values for the carbon/carbon laminates. A summary of the average elastic properties obtained is shown in Table 4. The property measurements obtained include shear modulus G_{12} and G_{21} . Poisson's ratios ν_{21} , ν_{31} were obtained for initial (approximately 50 percent of ultimate) loading of the tensile test.

All of the test results, Table 5, compare favorably with those previously reported for the carbon/carbon material, Reference 4. The density of the laminates varied from 1.50 to 1.51 gm/cc. The ultimate

tensile strengths ranged from 9,000 to 10,700 psi. The warp compressive strength was slightly higher ranging from 13,000 to 14,100 psi.

The fill tensile and compressive strengths were slightly lower than previously reported (Reference 4). The average fill tensile was 5,700 psi and the average fill compressive was 6,300 psi. Ultimate tension and compression results with the strain at failure are shown in Table 6. The maximum variation for strain at failure was the fill tension with variation ranging from 0.3 to 0.5 percent. It is assumed that this is characteristic, based on review of reported data for similar materials. An example of a stress/strain curve in tension for the carbon/carbon material is shown in Figure 12. The shape of the curve indicates stress/strain behavior becoming nonlinear at about 50 percent of ultimate.

The changes in moduli and Poisson's ratio at 75 percent of ultimate load and 100 percent of ultimate load are also shown in Table 4 along with initial straight line determinations. These values were used as the input for analysis to improve predictions of strain for cylinder tested to ultimate compression. The v_{13} and v_{23} values were not obtained at 75 and 100 percent of ultimate for tensile loading. The initial values were obtained on the compression specimens. The tensile specimens did not have strain gages in the cross ply direction.

The cross ply moduli in compression increased with load. All other moduli decreased with load. The increase in modulus is attributed to the compacting, which occurs in the porous matrix. As the load compacts the material, a rather high strain (2 percent at failure) is obtained. The porosity is reduced, and the reinforcement is loaded in intralaminar rather

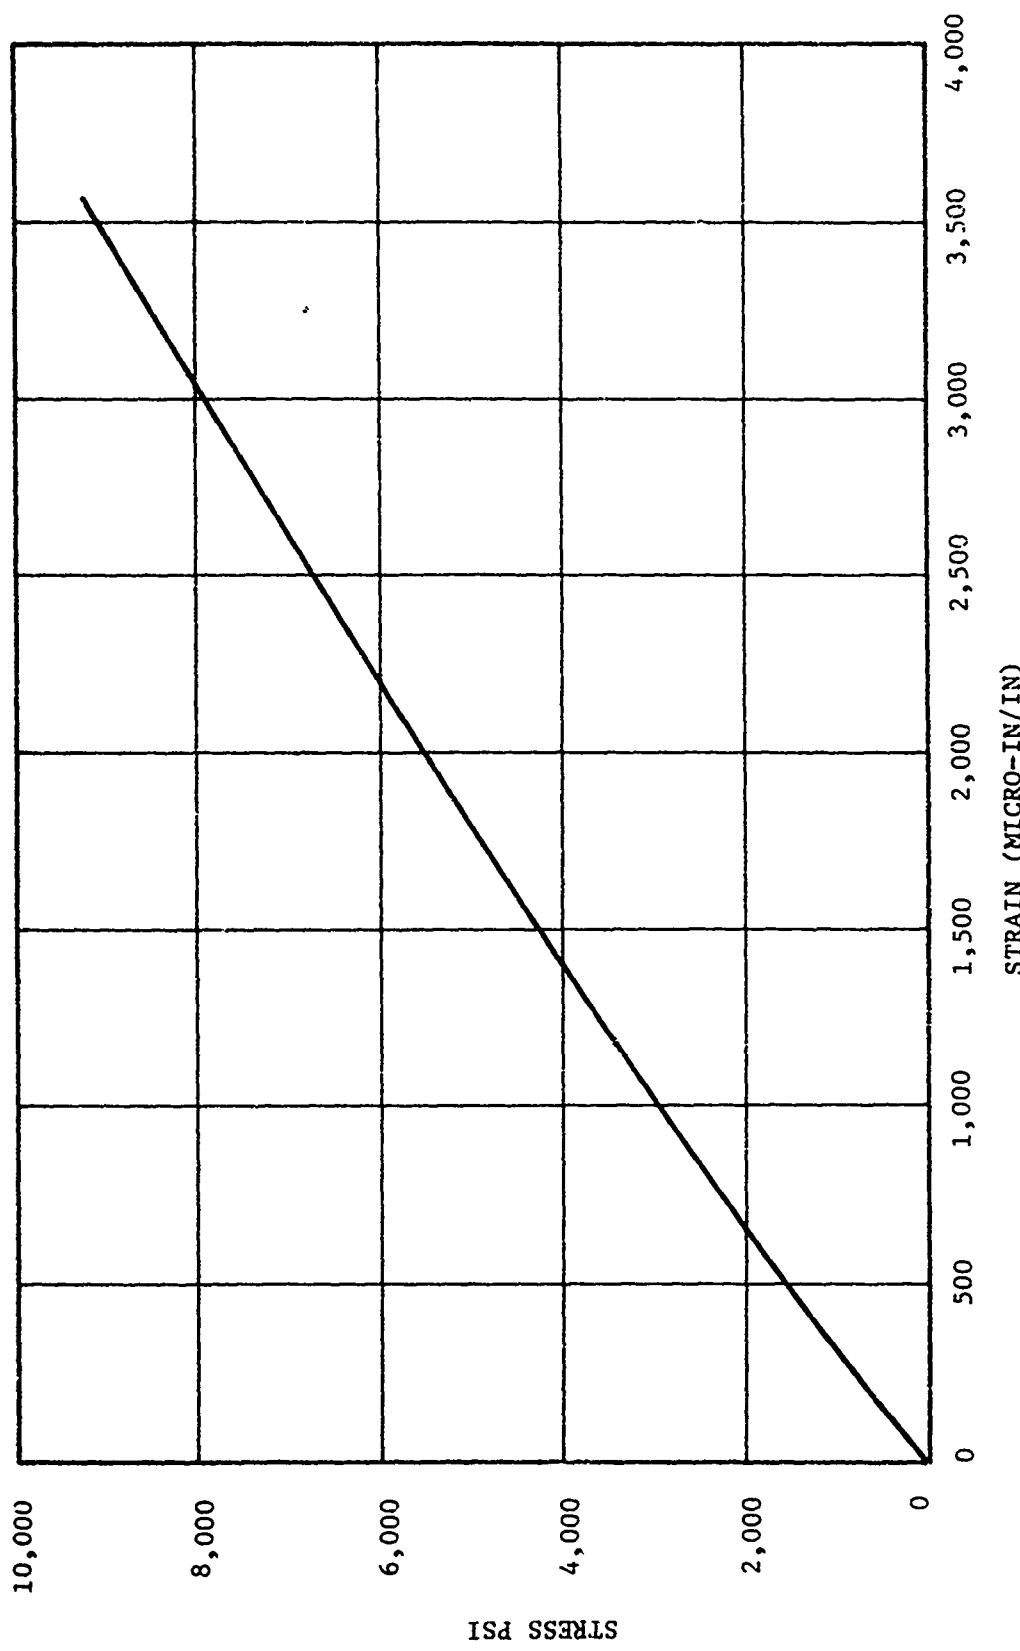

Figure 12. Typical Stress/Strain for Carbon/Carbon Tensile Loading - Warp Direction

than interlaminar shear, and the material becomes more rigid with load. The compression v_{13} and v_{12} also increase with load. The initial value was 0.23 and increased to 0.58 at failure for v_{13} .

All values obtained for initial straight line moduli, Poisson's ratios, and ultimate strengths are contained in Table 5.

A typical stress/strain curve for determination of initial shear modulus, G_{12} , is shown in Figure 13. All shear data were plotted, and G_{12} was calculated for the initial straight line as well as for 75 percent of ultimate to failure. The G_{12} shear moduli decreased from 0.6×10^6 psi to 0.3×10^6 psi.

A typical stress/strain curve for the carbon/carbon material loaded to failure in compression is shown in Figure 14. Average modulus values decreased from 2.8×10^6 psi to 2.5×10^6 psi at failure.

c. Tube Versus Laminate Data

The graphite/epoxy and carbon/carbon tube test in compression produced lower values than the laminate test for the warp or fill direction. The variation for the graphite/epoxy is discussed above. For the carbon/carbon the axial compression tube values were almost 4,000 psi lower than the laminate warp direction. However, the fill values were approximately the same (5,340 psi average for the tubes and 5,760 psi average for the laminates).

Based on these empirical results, it appears that the failure mode was the same for the fill specimens but not for the higher strength warp. It is likely that buckling occurred in the tube specimens where the warp is in the primary load direction.

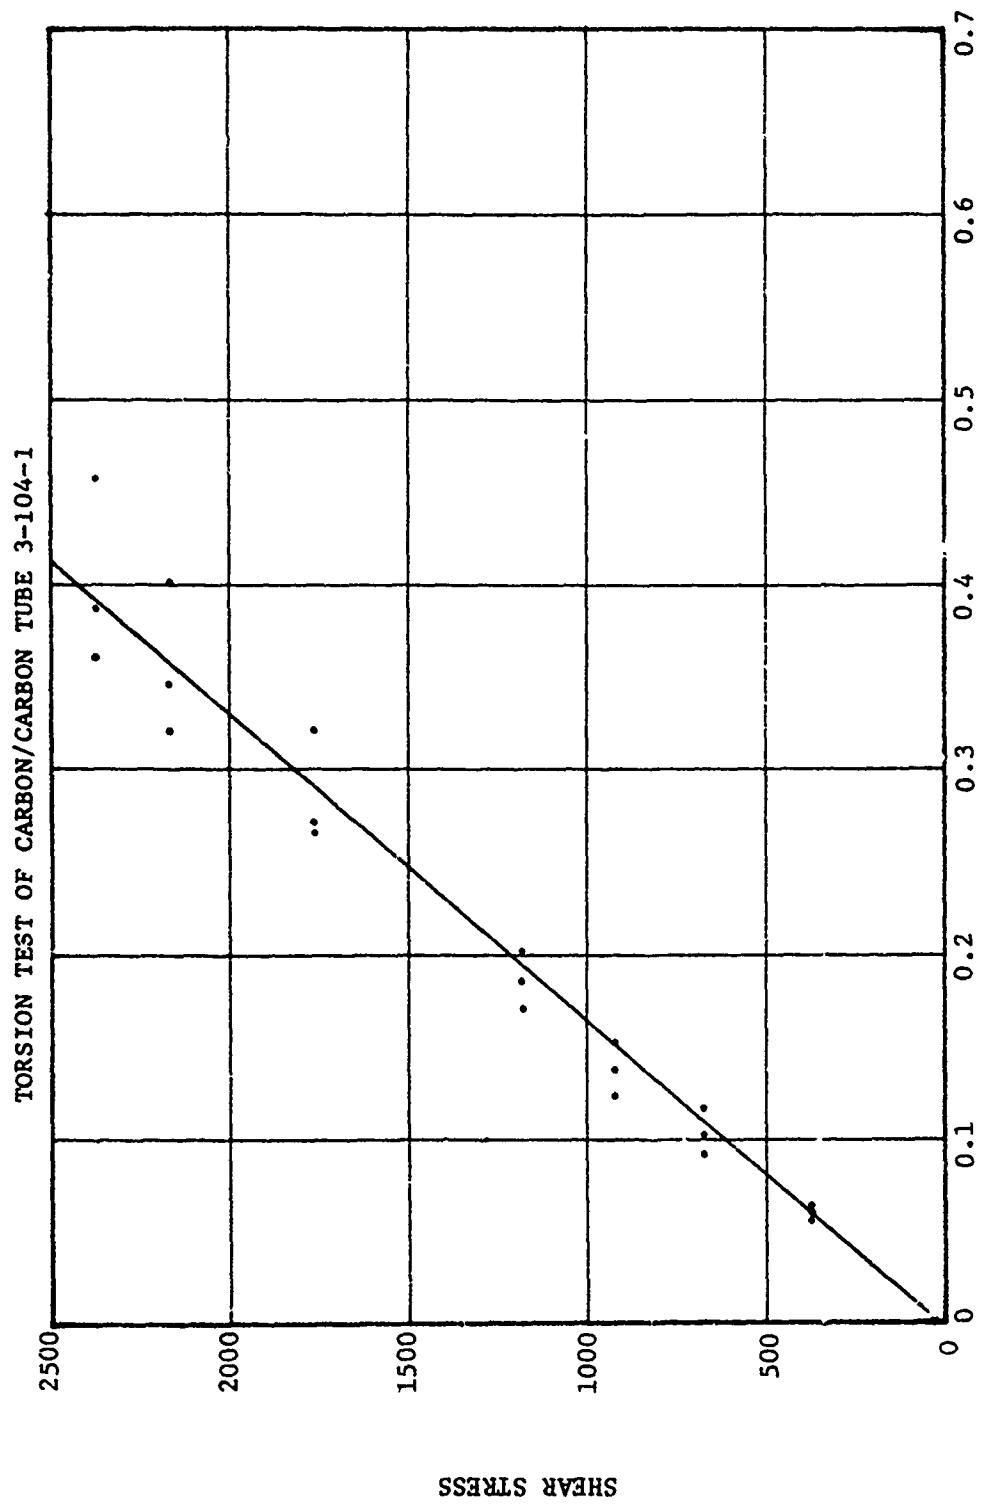

Figure 13. Typical Stress/Strain Curve for Shear Modulus Determination - G_{12}

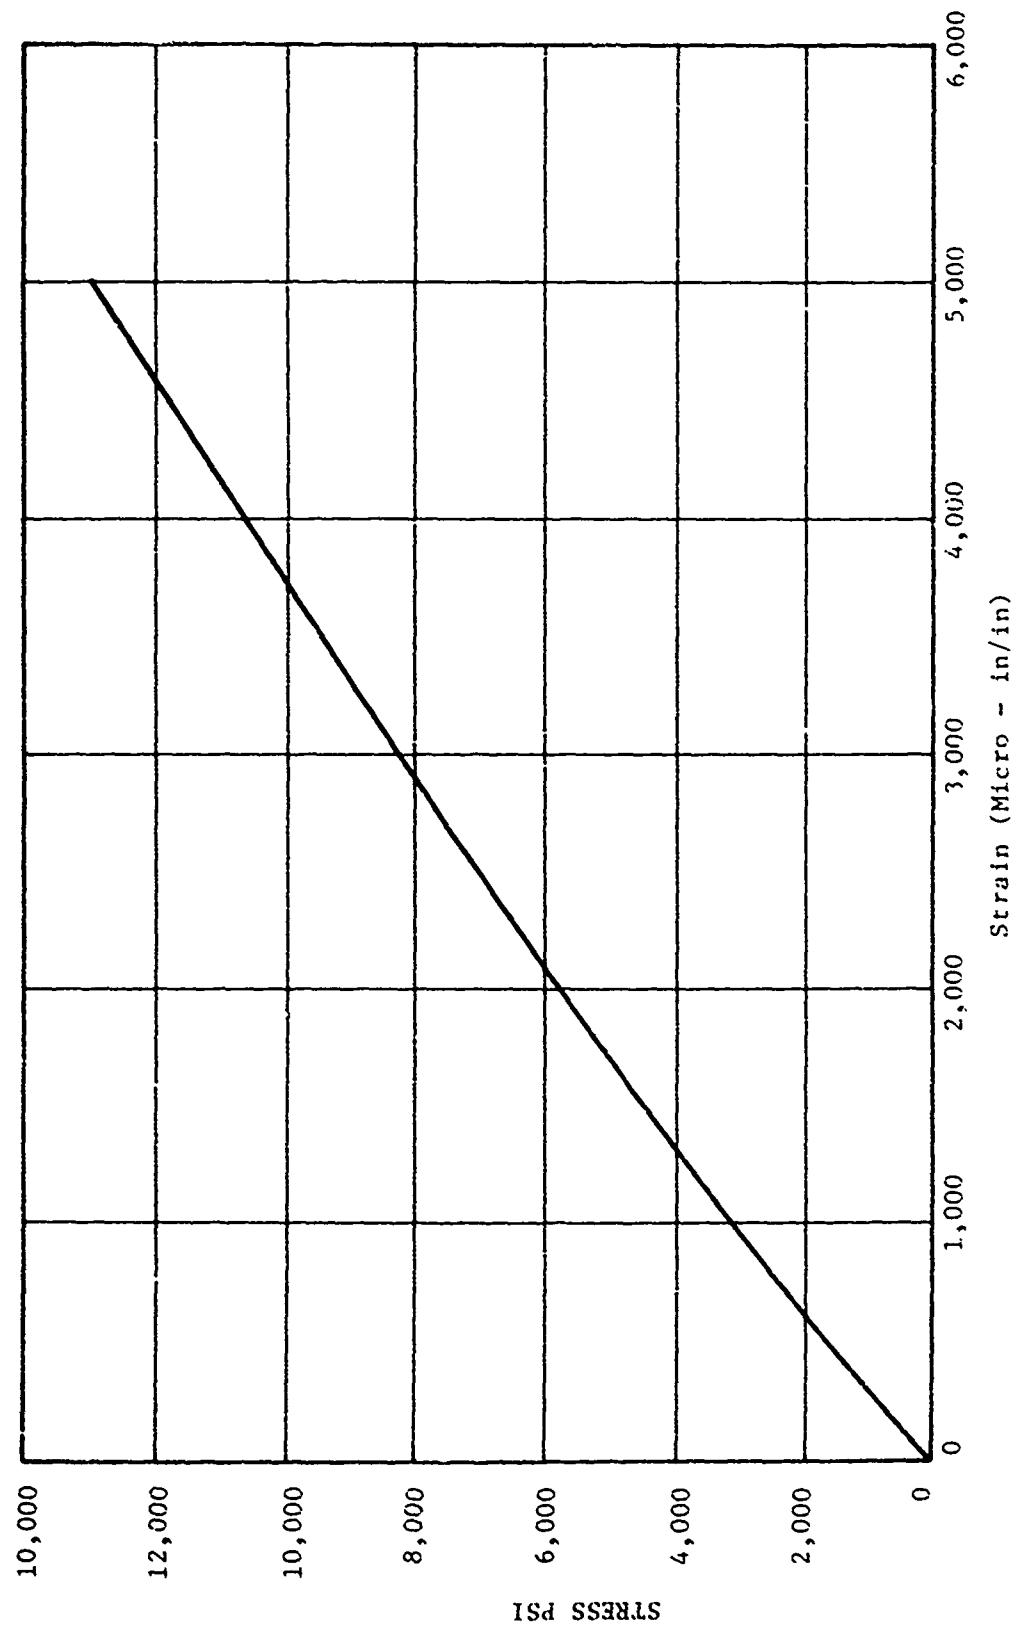

Figure 14. Typical Stress/Strain Curve for Carbon/Carbon Compression Loading to Failure - Warp Direction

The moduli and Poisson's ratio from laminates and tubes were in much better agreement. The tube moduli and Poisson's ratio were not used for prediction of behavior for the cylinders. However, it appears that either laminate or tube data could be used. For example, the warp modulus was 2.6×10^6 psi from the tubes and 2.8×10^6 psi for laminates. Fill modulus was 1.8×10^6 psi for the tubes compared to 1.74×10^6 psi for the laminates. The average Poisson's ratio ν_{12} from the tubes was 0.095, and from the laminate was 0.063. The tube ν_{21} was 0.097 compared to 0.18 from the laminates.

The tubes provided the only source for the G_{12} and G_{21} as well as the ultimate shear strength in torsion. All test results are listed in Table 5. The ultimate shear strength of 3490 psi is similar to the reported through fabric shear strength of 3800 psi, Reference 5.

d. Physical Property Measurement

The physical properties of selected specimens from laminates and tubes were documented. In general, results were satisfactory. One of the test specimens from the graphite/epoxy laminate had a relative low fiber volume percentage; however, all the mechanical properties taken from this laminate were satisfactory. There were no anomalies recorded for the carbon/carbon laminates and tubes which were tested.

(1) Graphite/Epoxy

The specific gravity, resin solids, fiber volume, and void content were determined on five specimens. With the exception of test panel 101, the results were satisfactory. The results are shown in Section III C. Specific gravity was below 1.60 for TP 101, and the percent resin was high, 36 percent. Apparently, the area tested did not bleed resin as well as the remaining samples. Tensile, compression, and shear specimens

Reference 5: Data Reported by G. Lucido, Kaiser Aerotech, Telephone Conversation, February 1979.

were taken from this laminate. The values obtained did not indicate an unsatisfactory test panel. The retest for specific gravity produced a value of 1.60. This indicates an edge effect on the test panel designated 101 with the outside edge being high in resin. This could have been produced by either a lack of pressure or resin bleed during cure. It is not believed that mechanical properties were taken from material with the high resin condition.

(?) Carbon/Carbon

A specific gravity for carbon/carbon laminates and tubes ranged from 1.50 to 1.51. The range of values and density distribution for the 3 in. thick laminates was also 1.50 to 1.51. Density distribution was determined by slices from the 3 in. thick laminates.

Typical photomicrographs of the 3 in. thick laminates were also taken for documentation of the matrix/reinforcement characteristics. These photomicrographs were also used for comparison to a typical section of a carbon/carbon involute cylinder. The photomicrographs are shown in Figures 15 and 16. The typical void pattern in low density carbon/carbon was observed throughout the samples mounted for photomicrographs.

One of the contributing factors to the lower strength and modulus in the fill direction is also shown by Figures 15 and 16. The fill yarns have the typical greater bend height and smaller radius. This results from the greater shrinkage of the fill yarns during the conversion processing from rayon to graphite.

e. Thermal Expansion

Thermal expansion measurements in the warp, fill, and crossply directions were made for both the graphite/epoxy and carbon/carbon

Figure 15. Carbon/Carbon Photomicrographs 100X Showing Bend in E111 Yarns and Voids (Dark Areas) in Warp Yarn Matrix - Typical

Figure 16 Carbon/Carbon Photomicrographs 100X Showing Bend in Warp Yarn and Voids (Dark Areas) in E111 Yarn Resin Matrix - Typical

materials. The temperature range for the graphite/epoxy was RT to 350°F and RT to 5000°F for the carbon/carbon materials. A quartz dilatometer was used for the graphite/epoxy and for the carbon/carbon up to 1500°F. The carbon/carbon specimen was also evaluated from RT to 5000°F in a graphite dilatometer.

The results are presented in Figure 17 through 24. Curves are plotted as unit thermal expansion (in./in.) versus temperature (°F). As expected the greatest thermal expansion is in the crossply direction for both the graphite/epoxy and carbon/carbon material.

The effects of weave, concentration of warp and fill yarns, and type of matrix were demonstrated in the values obtained. For example both weave and yarn concentration effects are shown in comparing warp to fill unit thermal expansion for the graphite/epoxy. At 350°F the unit thermal expansion for the fill direction (Figure 17) is 5.5 times the warp direction (Figure 18). The warp to fill weave count is four to one. The crossply unit thermal expansion (Figure 19) at 350°F is 45 times that of the warp. All three unit thermal expansion curves are shown in Figure 20.

The carbon/carbon anisotropy in thermal expansion is not great. At 4500°F the fill is only slightly higher than the warp and the crossply unit thermal expansion is only 1.6 times that of the warp direction. The warp thermal expansion is shown in Figure 21 and, the fill in Figure 22. The crossply specimen thermal expansion peaked at 4500°F (maximum process temperature) and started to shrink as shown in Figure 23. This behavior of slope change for thermal expansion is characteristic of carbon/carbon materials when the maximum process temperature is exceeded. The change is evidence of additional crystalline structure change at the higher temperature. The comparative unit thermal expansion for the carbon/carbon material is shown in Figure 24.

f. Observation of Failed Surfaces

The method selected to document the condition of the failed shear surfaces was photographs using a scanning electron microscope at the University of California at Davis, California. These and other photographs were also observed in a stereo setup using two photographs taken of the same area at different angles. The depressions and fiber or resin surfaces can be better isolated by this technique. A graphite/epoxy rail shear surface magnified 1000 times is shown in Figures 25 and 26. Figure 25 shows the failed resin surface with imprint (striation) from the fiber surface and irregular tensile failed surface of the resin. The fiber surface striations are across the photograph, left to right. There is some resin debris on the surface.

The warp yarn surface is shown in Figure 26. The tensile failure of the resin is shown in the left-handed side of the photograph, top to bottom. The right-hand side shows broken yarns at the shear surface; shear load was right to left on the photograph. Small particles of resin debris are also shown on the failed surface.

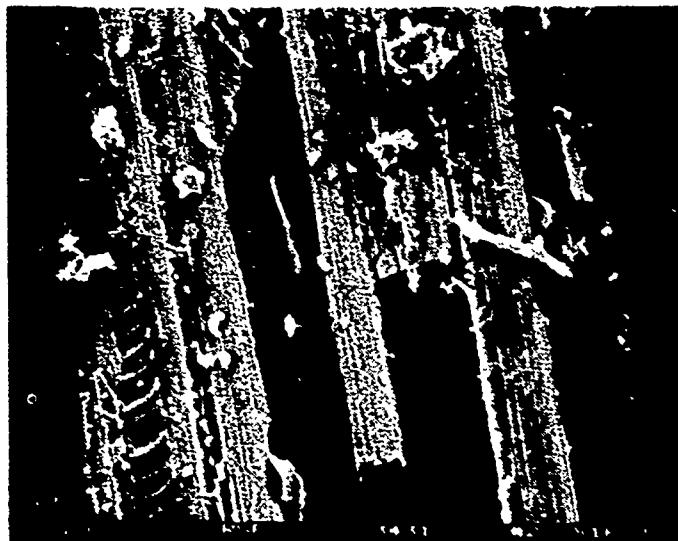

The shear surface of the carbon/carbon rail shear is shown in Figures 27 and 28. Figure 27 shows warp filaments (two failed) and imprint of the filament. The texture of the imprint is indicative of a sheath around the filament which is less porous than the majority of the matrix. The matrix does not have the characteristic appearance of tensile failure as shown by the graphite/epoxy resin.

The fill filament surface is shown in Figure 28. At the extreme left side of the photograph is a filament broken in the axial plane. The filaments appear to have matrix material attached to the crenulated surfaces in varying thicknesses. Although not shown, it was observed that some warp yarns have completely failed in tension. Fill yarns tended to be partially missing where they were on the failed surface, indicating some shear

load through or into the yarn bundle. This is characteristic of nested fabrics tested in interlaminar shear, but it could not be determined if the yarn damage occurred after failure or at initial failure.

D. TESTING OF CYLINDERS

The graphite/epoxy and carbon/carbon involute cylinders were tested in accordance with the matrix shown in Figure 5. The deflection and strain measurement for the uniaxial loading was duplicated for:

1. Axial tension
2. Axial compression
3. Torsion
 - a. Clockwise
 - b. Counterclockwise
4. Hoop Tension

Figure 29 shows the relationship of the warp and fill orientation to the strain gage indications. The 45-degree gage was parallel to the fill yarn for all 45 degree helix tests. Strain gages were located at 0, 120 and 240 degrees for all testing. The ply orientation in relation to the clockwise and counterclockwise torsion testing is also shown in Figure 29. Torsion loading was applied at the top of the cylinder. The combined loading included the following:

1. Axial Tension/Internal Pressure
2. Axial Compression/Internal Pressure
3. Clockwise Torsion/Internal Pressure

As for the uniaxial testing, the combined loading testing was conducted on at least two cylinders.

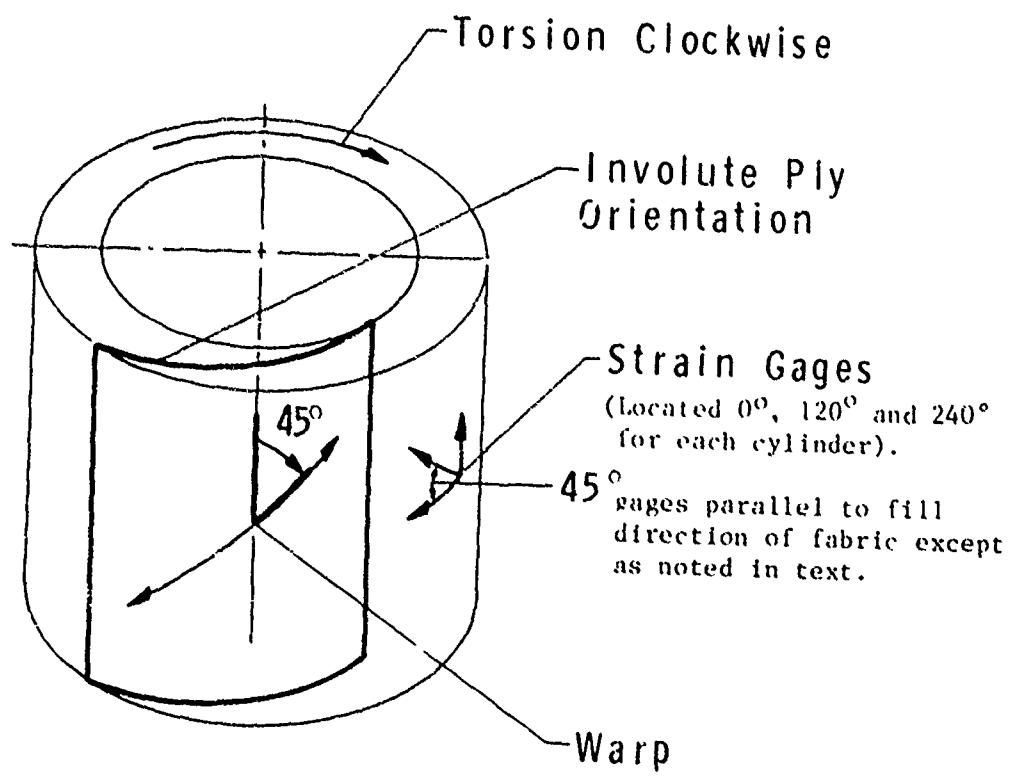

Figure 29. Strain Gage Location and Warp/Fill Orientation for 45° Helix Cylinders

Three cylinders were used for all of the graphite/epoxy testing. There were 15 cylinders of the carbon/carbon materials, five each of the (1) 10 degree arc/45 degree helix, (2) 5 degree arc/55 degree helix and (3) 10 degree arc/0 degree helix. Two of the graphite/epoxy cylinders were tested to failure, and all 15 of the carbon/carbon cylinders were tested to failure.

The cylinders were machined to contour as shown in Appendix A. Steel sleeves were bonded to both ends 1D and 1D of the cylinders using a trowelable epoxy adhesive. The sleeves were then placed in a drill fixture and eight 0.625 in. dia holes were drilled through the steel sleeves. These holes were used for shear pin attachment to the holding fixture for compression, tension, and torsion testing. A photograph of the torsion test fixture with a cylinder assembled for test is shown in Figure 30. The test setup shown in Figure 30 was also used for torsion and internal pressure. The gas inlet tube is attached at the bottom of the fixture.

All load's applied to the cylinders with exception of the internal pressure testing were applied through the pins and sleeves bonded to the ends of the cylinders. To obtain uniform strain for tension and compression loading, specimens were preloaded, and adjustments were made in the pin fit-up prior to test. Additional cylinder length would reduce the pin fit-up and alignment problem.

The internal pressure was applied through a rubber bag inside the cylinder.

The loading for compression, tension, torsion, and internal pressure was in incremental steps. Strain measurements were read from each of the nine strain gages by a data acquisition system prior to applying the next increment of load. The readout required maintaining the cylinder under a constant load for approximately 15 seconds prior to applying the next increment of load.

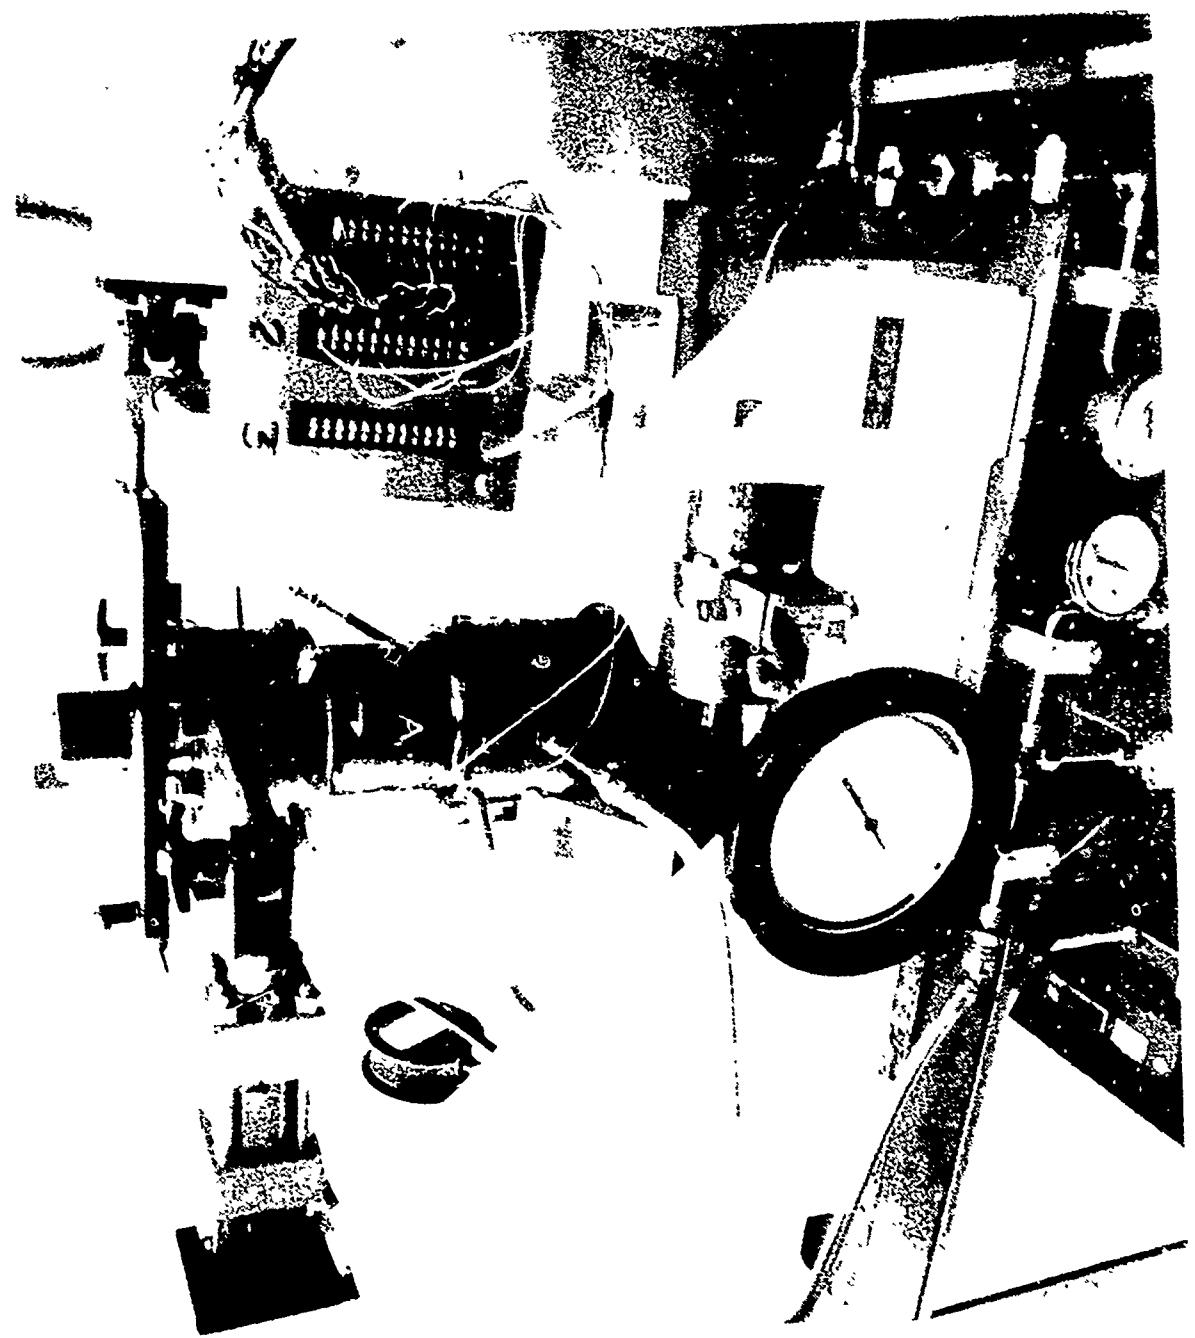

Figure 30. Torsion Test Fixture with Assembled Carbon/Carbon Cylinder Ready for Test with Attached Strain Gages

1. Graphite/Epoxy

The test plan previously discussed is shown in Figure 5.

Each specimen was loaded twice per test plan. Two of the graphite/epoxy cylinders, 5 degree arc/45 degree helix and 10 degree arc/45 degree helix, were tested to failure in compression. The ultimate strengths were very low compared with the warp compressive strength. The ultimate strengths were 26,700 and 27,000 psi, respectively, for the 10 degree arc/45 and 5 degree arc/45 helix degree cylinders. A buckling failure (possible shear) with cross ply delamination was the observed failure mode for the 10 degree arc specimen and to a lesser degree for the 5 degree arc specimen. The calculated modulus for the compression and tension loading of the 10 degree arc 0 degree helix cylinder was approximately 2.0×10^6 psi lower than for the laminates or tubes. Based on these results it is assumed the same low volume factors existed for the 0 degree helix cylinder as for the 45 degree helix cylinders discussed below. The measured strains for the uniaxial and combined loading are presented in Section E.

Predicted warp-fill shear stress at failure was 13,500 warp-fill for both cylinders which is near the warp-fill allowable of 17,200 psi. A significant factor which affected both ultimate strength and modulus was the high resin content/low fiber volume of the cylinders. The following average values were obtained from the 10 degree arc/45 degree helix sample.

<u>Property</u>	<u>Value</u>
Density, gm/cc	1.56
Fiber Volume, %	53.00
Resin Solids, %	39.60
Void Content, %	0.500

There was low void content, indicating good compaction during the cure/pressure cycle, but the fiber volume was low, and the resin content was high. These values indicate less resin bleedout during cure than was

obtained for the laminates and tubes. The average density for the laminates and tubes was 1.61 with a fiber volume of 61 percent.

The resin staging, discussed in Section B, used to prevent wrinkling of the graphite/epoxy plies apparently reduced the normal resin bleedout during cure. A review of the results indicates the low fiber volume affected the strain results for the 10 degree arc/0 degree helix and produced the lower modulus for the cylinder.

A graphic comparison of the measured versus predicted axial strain for hoop tensile testing of a graphite/epoxy cylinder is shown in Figure 31. Agreement is good; however, the measured strain is higher and increasing at a faster rate per unit load than the model prediction.

A predicted versus measured strain for the combined internal pressure and axial tension loading provides a very good agreement for the axial strain as shown in Figure 32. The remainder of the predicted versus measured comparisons for the graphite/epoxy are shown in tabular form in Section E.

2. Carbon/Carbon

The carbon/carbon cylinders were also tested in accordance with the test plan shown in Table 7. The reuse of cylinders for strain measurements was minimized for the carbon/carbon cylinders. The strain measurements are contained in tabular form in Section E. Agreement of predicted with measured strain is also discussed in the analysis section; however, some graphic comparisons are presented in the following discussion.

The density determinations from a sampling of the carbon/carbon cylinders indicate a somewhat lower density than that measured for the

laminate. A value of 1.48 gm/cc was obtained from the test cylinders compared to 1.50 and 1.51 from the carbon/carbon test laminates. Previous comparisons of cones and laminates have shown equivalent densities. The cause of the slightly lower density could not be determined; however, the effects on mechanical properties were not considered significant based on previous tests of the carbon/carbon material, Reference 4. A reasonable density tolerance to be expected is +0.02/-0.02 gm/cc. The tolerance estimate is based on experience and not a controlled experiment.

Figure 33 shows a cylinder assembled and ready for testing. Loading of the carbon/carbon cylinders was in increments, allowing for data collection at each load. Slightly higher ultimate strengths would possibly have been obtained for a continuous load to failure.

The ultimate strength values for the carbon/carbon cylinders are listed below for each of the three involute variations.

Type Test	Involute Arc, Degrees	Variation, Degree Helix	Ultimate Strength, psi

	10	45	5303

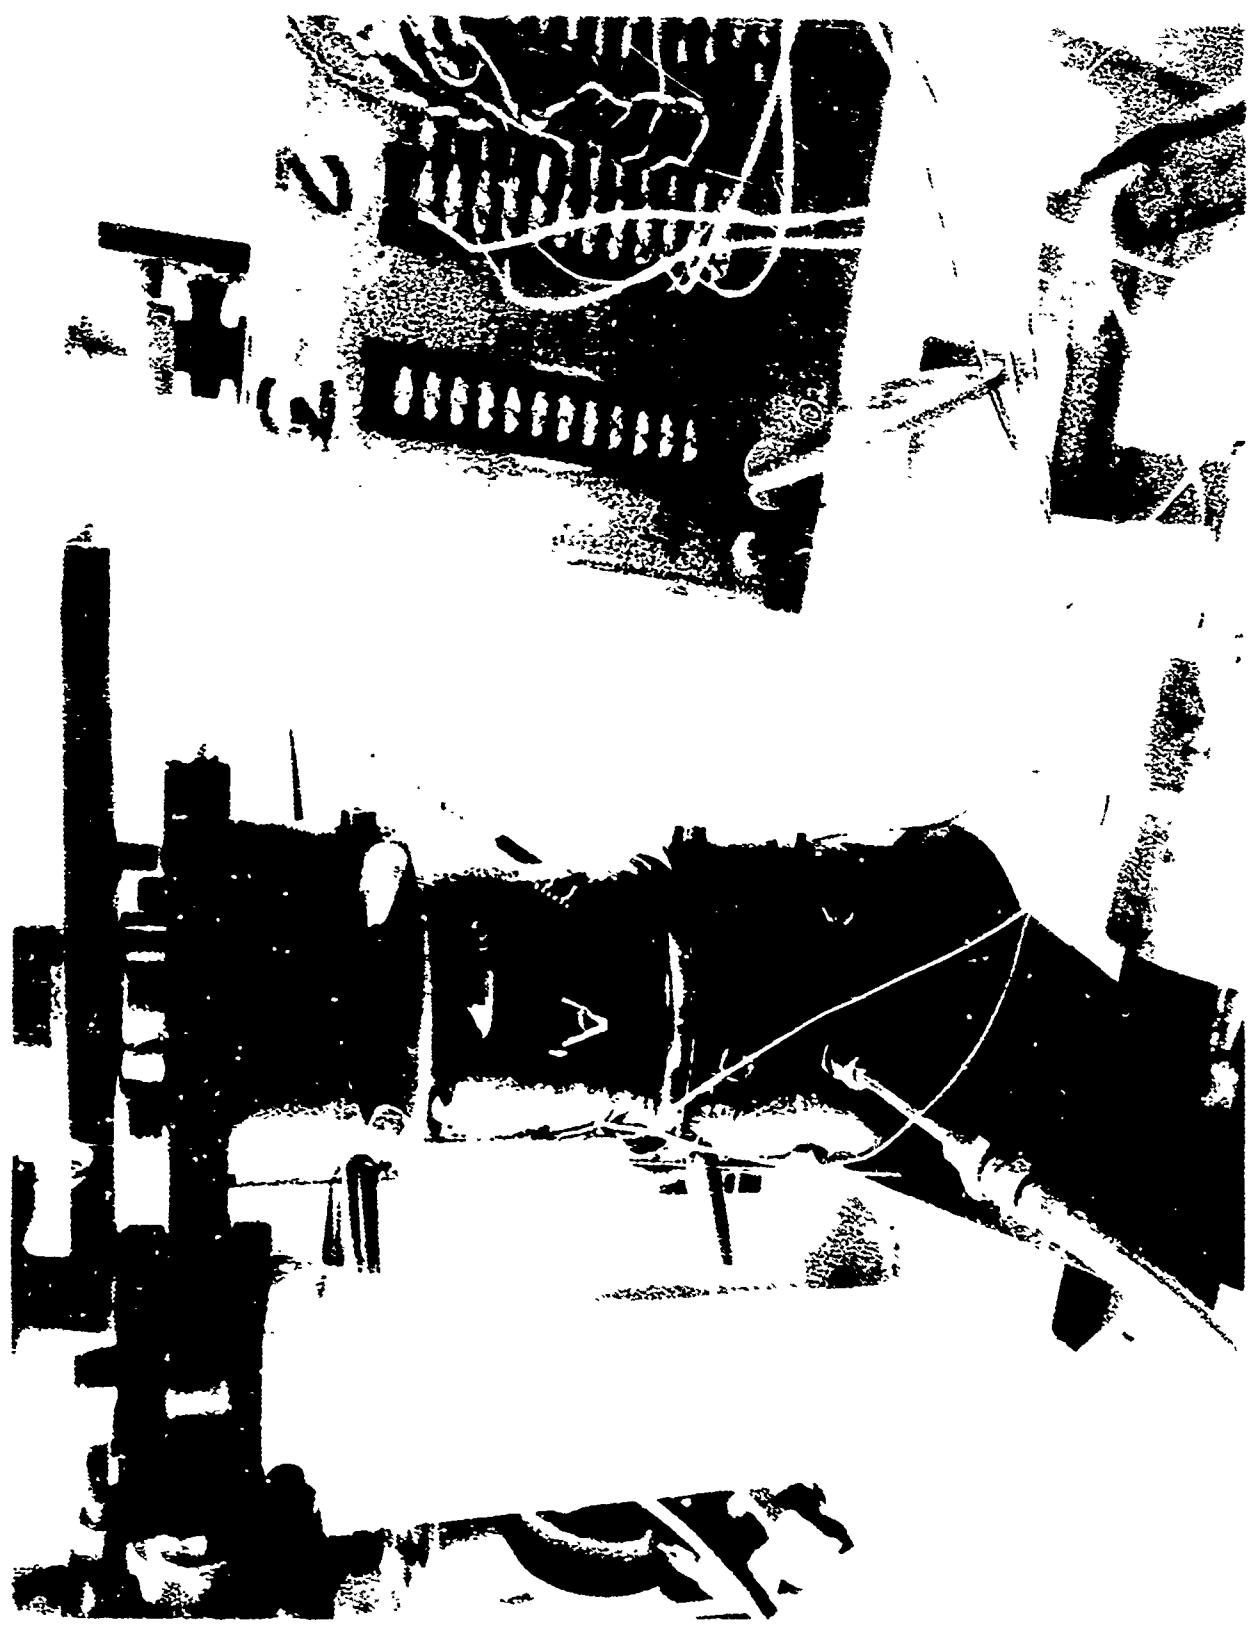

Figure 33. Carbon/Carbon Test Cylinder Assembled for Combined Torsion/internal Pressure Loading

All of the measured stresses at failure are also shown in Table 18 in Section E. Based on limited previous test data, the ultimate strengths indicate acceptable values were obtained for all cylinders, with the exception of two cylinders. The hoop tensile (internal pressure) specimen for the 5 degree arc/45 degree helix was damaged subsequent to the intermediate test loading, and no value for ultimate hoop tensile strength was obtained. In addition, the axial tensile test of the 10 degree arc/0 degree helix produced a low ultimate strength, 7777 psi, compared with 9950 psi average for the laminate test in the warp direction. This was the first cylinder tested in tension, and difficulties were encountered in obtaining good alignment as evidenced by the large variation, approximately 15 percent, in the axial strain gage indications. There was only one specimen per each type of ultimate test; therefore, a determination of the effect of misalignment could not be ascertained. All subsequent tests were aligned to control strains within 10 percent prior to loading for data collection.

A photograph of the tensile failure of 5 degree arc/45 degree helix specimens is shown in Figure 34. The failure surface parallel to the warp yarns is more uniform than on the opposite side parallel to the fill in the fill yarns. However, it can only be postulated that failure initiated at this point. Another failure mode could have been initial failure of both warp and fill yarns and propagation along the 45 degree helix on both sides of the cylinder. Figure 29 was used as a reference of the warp-fill orientation for comparison with the failed surfaces.

A failed axial compression specimen is shown in Figure 35. The failure appears to have been typical shear with some delamination evident. Occurrence of delamination prior to initial failure is not likely because of the predicted low interlaminar shear cross ply tension. The buckling that was observed on the graphite/epoxy was not evident. The predicted failure modes are shown in Table 18.

Figure 34. Tensile Failure 3° Arc/45° Helix Showing Some Tensile Failure Parallel to Helix Angle (piece on left is top of cylinder)

Figure 3 Axial Compression Failure, 10° Arc / 0° Helix, Typical Shear Surfaces and Strain Gages at 120° Location

A failed hoop tensile (internal pressure) specimen is shown in Figure 36. Characteristically, approximately one half of the specimen was blown out and broken into pieces at failure. The failed pieces were also delaminated. Some of the remaining failed surfaces are also interlaminar separations.

All three types of involutes tested in torsion are shown in Figures 37 through 39. Figure 37 is a 10 degree arc/45 degree helix. Figure 38 is a 5 degree arc/45 degree helix, and Figure 39 is a 10 degree arc/9 degree helix. Each of the photographs shows different failure patterns. The limited experience in testing carbon/carbon cylinders in torsion makes it difficult to draw valid conclusions about the specimen appearances and the complicated loading. There appears to be some delamination (separation between plies) for all of the specimens. Separation between plies was also present, but to a lesser extent, in the 10 degree arc/0 degree helix specimen. The failure shown in Figure 39 appears to be tensile failure of the fill yarns. (The same failure characteristic was observed on one of the graphite/epoxy tube torsion degree tests, Section C.) The most likely failure mode for the 0 degree helix cylinder is warp-fill shear failure as shown in Table 18. Both of the 45 degree helix cylinders had high fill fiber tension stress, Table 18. The effects of variation in the helix angle are discussed in Section III, D.5.

Two of the cylinders were sectioned to verify the warp and fill direction specified. Photomicrographs of the sectioned cylinders are shown in Figures 40 and 41. Observation of the cross sectioned cylinders verified that the warp/fill relation was as specified and as reported by the fabricator. Rough measurements of the helix angles both from the sectioned pieces and surface condition indicate warp and fill helix was 45 ± 5 degrees. It is not believed that it would be possible or practical to obtain cylinder lay-ups with closer tolerances on the helix angles. Some distortion of the

fill yarn exists in the as processed condition. The fill yarns are not always perpendicular to warp yarns in the as graphitized fabric. Furthermore, some distortion results from handling during the prepeg operation as the fabric is passed through the resin and drying ovens.

The matrix contains irregular voids (density is 1.45 gm/cc) that extend into, and in some cases, through the yarn bundles. In Figures 40 and 41 the dark areas are voids, gray areas are matrix, and the light irregular shapes are ends of graphite filaments. The white areas, continuous from right to left, are fill yarns in Figure 40 and warp yarns in Figure 41. This is characteristic of the 2D carbon/carbon material in both laminates and cylinders. The appearance of the matrix that encapsulates the yarn bundle was very similar to the cross section of the test laminates which were previously discussed and shown in Figures 15 and 16.

The measured and predicted ultimate strength values for all cylinders are contained and discussed in Section E. Selected, predicted, and measured values were also plotted and are discussed herein. The agreement for predicted and measured strain is very good for the axial compression test of the 0 degree helix cylinder as shown in Figure 42. The measured strain is only slightly higher at failure.

Conversely, the agreement at failure for the compression testing of a 45 degree helix is very poor as shown in Figure 43. However, the agreement is satisfactory up to approximately 75 percent of ultimate. A method that improves the prediction is discussed in Section E. Another comparison of predicted versus measured strain, at 45 degrees to load, is shown in Figure 44. The agreement is adequate up to 50 percent of ultimate, but deviates significantly above 50 percent.

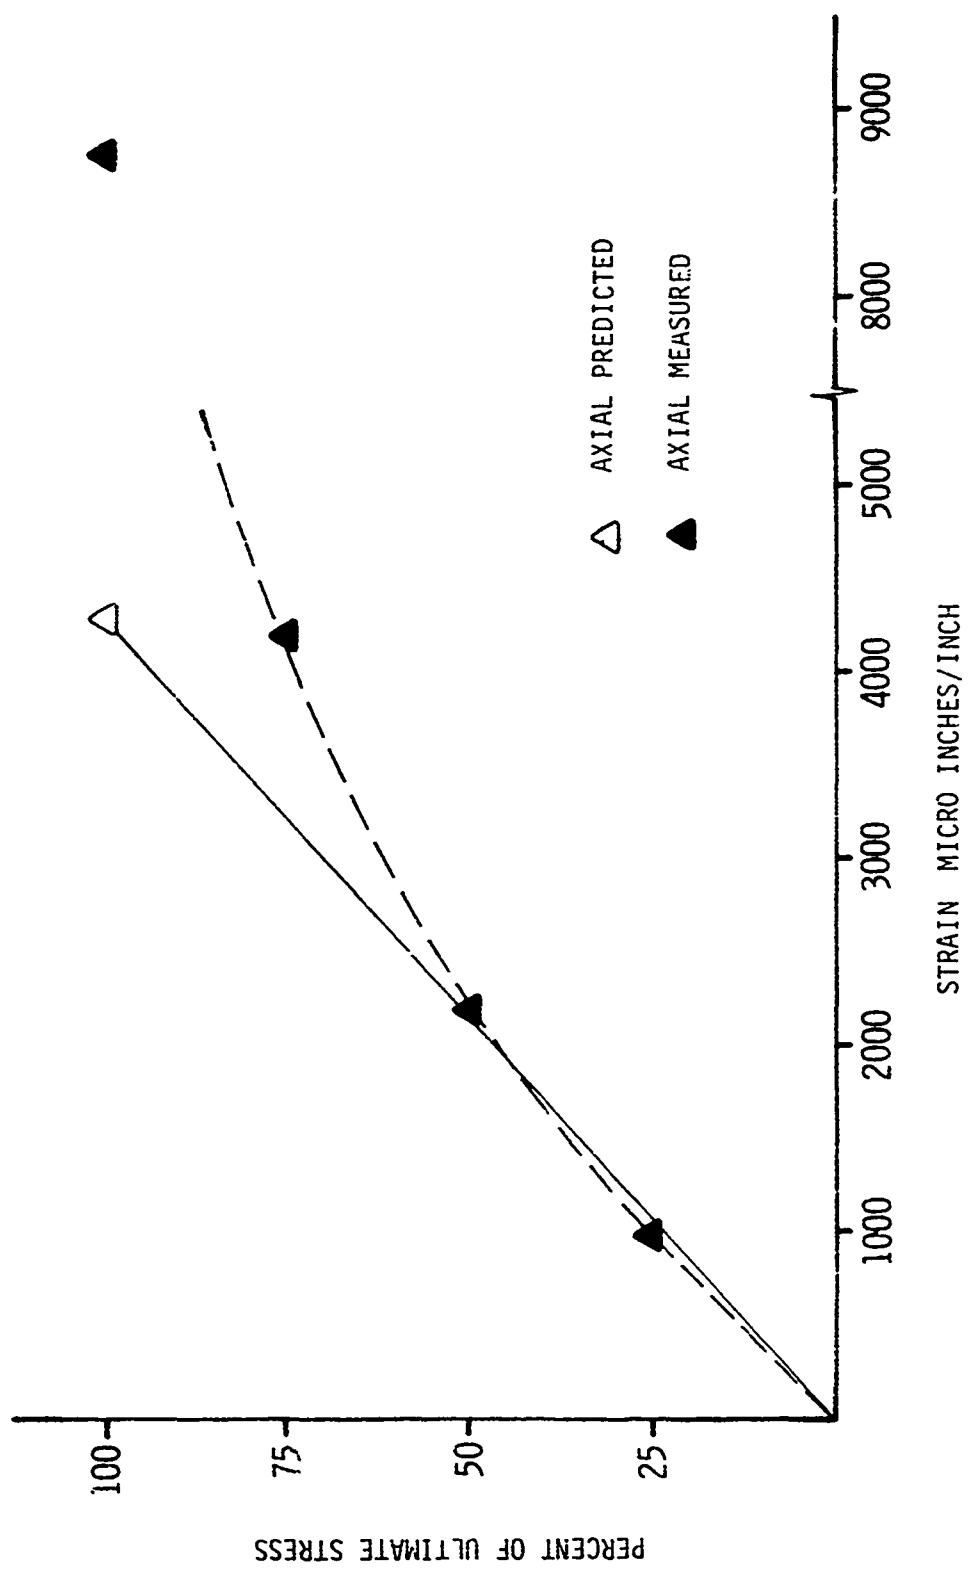

Figure 45. C/C, Involute Cylinder, 5° Arc, 45° Helix, Load: Axial Tension

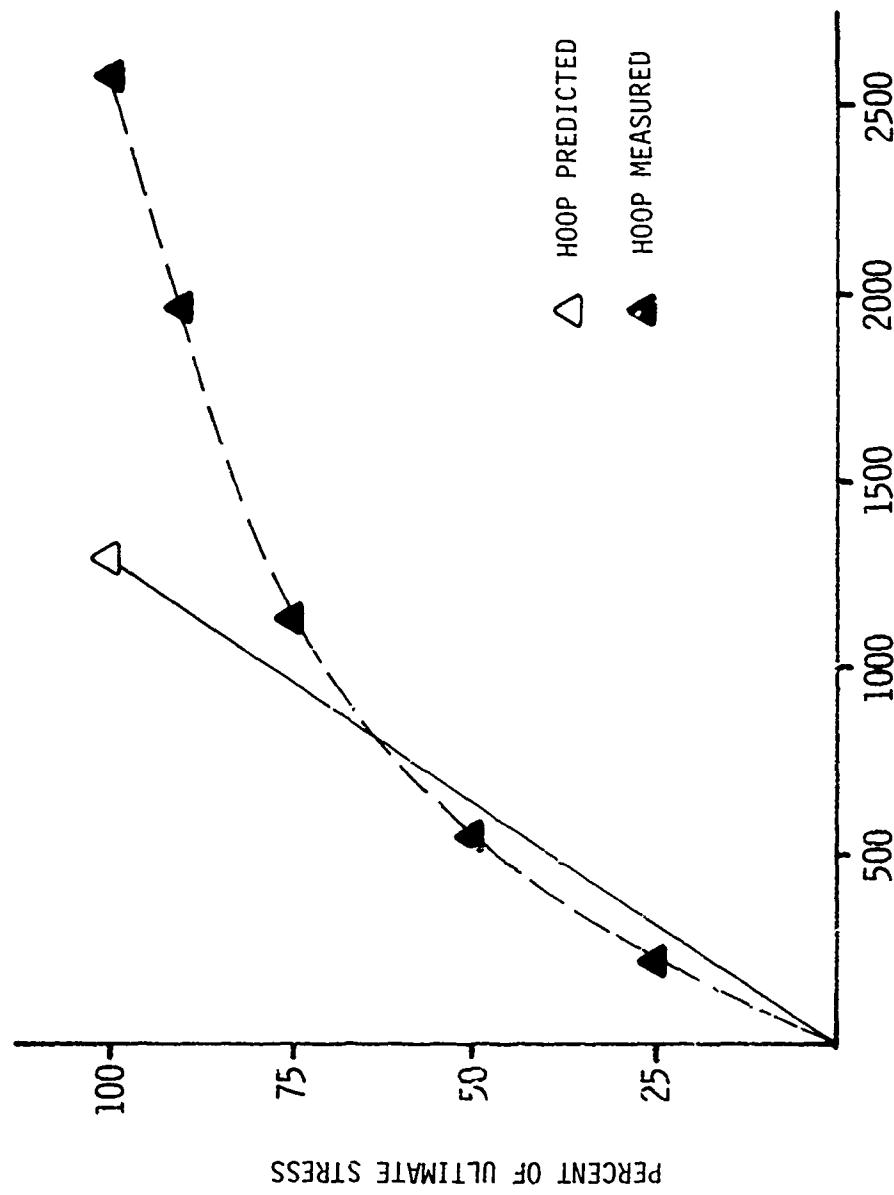

Figure 46. C/C, Involute Cylinder, 10° Arc, 45° Helix, Load: Axial Compression

Agreement for the predicted versus measured strain for tensile testing of the 5 degree arc/45 degree helix (Figure 45) is also good up to 50 percent, but deviates extremely above 50 percent of the ultimate. The measured strain is approximately twice that predicted at failure. During test, sharp sounds were produced at approximately 80 percent of ultimate, indicating local failure, but the cylinder continued to support increased load.

The measured hoop strain versus predicted strain for an axial compression test is shown in Figure 46. Agreement is satisfactory to approximately 70 percent of ultimate, but deviates by about 100 percent at failure.

Better agreement for all predicted versus measured might be achieved by using the nonlinear technique discussed in Section E.

E. PREDICTION OF CYLINDER BEHAVIOR AND CORRELATION RESULTS

The techniques used to predict the structural response of both the carbon/carbon and graphite/epoxy cylinders to tensile and compressive axial, clockwise and counterclockwise torsional, and internal pressurization applied loads are discussed in this section. For each cylinder material three combinations of helix angle and involute arc angle were tested and analyzed. All predictions were made using the computer code received from AFML (Reference 6) converted to the UNIVAC 1108 computer.

The AFML computer code solves a one dimensional linear elasticity problem by the finite difference method. It allows orthotropic materials to be used and uses nine independent constants in the stiffness matrix. Applied loads (torque, axial load, internal and external pressure) are entered directly, after a set of influence coefficients is calculated which relate these applied loads to the displacement boundary conditions. Table 8 shows the relationship between these boundary conditions and the influence coefficients required as input to the code. The assumption of linear behavior of the code was used in all the predictive results with the exception of the nonlinear modification discussed in Section III, E.3.

For each material and cylinder configuration, unit solutions were obtained. These unit solutions were the elastic structural response to a 10,000 lbf axial load, a 10,000 in.-lbf torque, and 1000 psi internal pressure. The unit solutions were then scaled and combined to correspond to each specific test prediction. For each test "point" (cylinder load) the strain readings at the outer surface were taken as the averaged values of the three rosette strain gages located at the 0, 120, and 240 degree circumferential locations, for the axial, circumferential, and 45 degree directions. Strain

Reference 6: Computer Code received from N.J. Pagano, AFML, February 4, 1977.

predictions for the axial and circumferential directions are taken directly from the computer output, and the strain at 45 degrees is calculated from

$$\epsilon_{\beta} = \frac{\epsilon_z + \epsilon_0}{2} + \left(\frac{\epsilon_z - \epsilon_0}{2} \right) \cos 2\beta + \frac{1}{2} \gamma_{z0} \sin 2\beta$$

with $\beta = 45$ degrees.

1. Graphite/Epoxy Cylinders

The ASPC 3431 graphite/epoxy cylinders were modeled using the cylinder dimensions (Appendix A). The three combinations of helix and arc angle fabricated for testing and analysis and their designations and descriptions are summarized below:

GRAPHITE/EPOXY CYLINDER DESCRIPTIONS					
Specimen Designation	Helix Angle, Deg	Arc Angle, Deg	Ply Thickness, in.	Mean Number of Plys	Initial Arc Angle, α_0 , Deg
A	45	5	.007	172	4.8
B	0	10	.007	324	9.06
C	45	10	.007	324	9.06

The following nine elastic constants for graphite/epoxy were used to analyze all three cylinders:

$$E_{11} = 16.8 \times 10^6 \text{ psi} \quad G_{12} = 1.15 \times 10^6 \text{ psi} \quad v_{12} = 0.04$$

$$E_{22} = 5.0 \times 10^6 \text{ psi} \quad G_{13} = 0.70 \times 10^6 \text{ psi} \quad v_{13} = 0.06$$

$$E_{33} = 1.6 \times 10^6 \text{ psi} \quad G_{23} = 0.65 \times 10^6 \text{ psi} \quad v_{23} = 0.023$$

TABLE 8. INFLUENCE FUNCTIONS

Assume $B = D = 0$

Let P, T = Prescribed Values

$\sigma, A, \sigma_0, \sigma_1$ = Values Corresponding to P, T

P_1, T_1 = Values Corresponding to $\epsilon = 1, A = \sigma_1 = \sigma_0 = 0$

P_2, T_2 = Values Corresponding to $\epsilon = 0, A = 1, \sigma_1 = \sigma_0 = 0$

P_3, T_3 = Values Corresponding to $\epsilon = A = 0, \sigma_1 = 1, \sigma_0 = 0$

P_4, T_4 = Values Corresponding to $\epsilon = A = \sigma_1 = 0, \sigma_0 = 1$

$$\epsilon = \frac{(P - \sigma_1 P_3 - \sigma_0 P_4) T_2 - (T - \sigma_1 T_3 - \sigma_0 T_4) P_2}{P_1 T_2 - P_2 T_1}$$

$$A = \frac{(T - \sigma_1 T_3 - \sigma_0 T_4) P_1 - (P - \sigma_1 P_3 - \sigma_0 P_4) T_1}{P_1 T_2 - P_2 T_1}$$

Where P = the applied axial load
and T = the applied torque

where the subscripts "1", "2", and "3" again refer to the warp, fill and crossply directions, respectively. The "unit" solutions corresponding to a 10,000 lbf axial load, a 10,000 in-lbf torque, and a 1000 psi internal pressure are summarized in Table 9. For comparing measured to predicted data, the data from the three strain gages were averaged at each test point and these averaged values compared to the predictions. The comparisons are shown in Table 10.

All strain measurements did not agree with the predicted strains for the graphite/epoxy. The 45° strain measurements were not in good agreement for the tension and compression loading of the 45° helix cylinders. The measured strains were consistently higher than those predicted. The sensitivity study, Section III, E.5, for a C-C 45° helix cylinder offers possible explanation, particularly for any deviation of warp-fill direction or strain gage direction.

Strain readings had different signs. For example, the compression/internal pressure combined loading of 10 degree arc 0 degree helix specimen B-2-106-1 produced a measured negative strain of -81 micro-in. and the predicted was +17 micro-in. The inaccuracies at this level are considered insignificant and are likely a result of the difficulty in obtaining reproducible strain readings at such low strains. Similar small disagreements were shown for the torsion of the 10 degree arc 0 degree helix. The Z and θ predictions, Table 10, are zero for all load increments. Measured values from 0 to 49 micro-in were obtained for the hoop direction. Measured values for Z direction ranged from 116 to 156 micro-in. These positive values are average and could be attributed to low bending loads, but the values are very low, and the differences are not considered to be significant.

There are also some relatively large discrepancies between measured and predicted strain in the Z, θ, and 45 degree directions as shown

In Table 10. Tension loading of the 45 degree helix cylinders produced up to 100 percent variations in θ strain for the 45 degrees cylinders. Measured values were higher than predicted (-1756 micro-in./in. compared with -992 micro-in./in.) and (-2033 micro-in./in. compared with -1079 micro-in./in.). Similar results were obtained for compression loading; however, the discrepancy was not as large.

The measured δ for the 45 degree helix is in better agreement with the tension and compression loading. The effect of variation in the helix angle was not determined for the graphite/epoxy either by testing or analytically. However, based on the sensitivity discussed below for carbon/carbon, additional testing for verification and more comprehensive sensitivity studies, including helix angles other than 0 and 45 degrees, are needed to satisfactorily resolve the large differences in the measured and predicted values for the high modulus graphite/epoxy material.

The torsion and combined torsion/pressure also produced some variations between predicted and measured strains. The measured 45 degree strains were generally higher than predicted. The 45 degree helix cylinders had measured strains of \sim 500 micro in./in. and predictions were \sim 250 to 300 micro-in./in. The 0 degree helix cylinder had measured strains of 2000 to 2500 micro in./in. with predictions from 1441 to 1621 micro-in./in., depending on the variation in load. The individual strain indications for the δ , θ , and 45 degree direction are shown in Table 10.

Agreement for combined torsion and internal pressure was comparatively good for most data points recorded. Measured values were generally higher than predicted.

Agreement was good for the two internal pressure tests. Measured values were only slightly higher than predicted. For the combined internal

pressure/tension and internal pressure/compression loadings, agreement between the measured and predicted strains was satisfactory. Again, measured values were generally higher than predicted values. The measured 45 degree strains for the 45 degree helix cylinders were relatively low, but in some instances almost twice the predicted values. These values again indicate the sensitivity of the gage and fiber direction for the large helix angles of the unidirectional high modulus reinforced epoxy material.

2. Carbon/Carbon Cylinders

The carbon/carbon cylinders were analyzed using the cylinder dimensions, Appendix A. The three combinations of helix and arc angle fabricated for test and their designations and descriptions are summarized in the table below:

K408A CARBON/CARBON CYLINDER DESCRIPTIONS

Specimen Designation	Helix Angle, Deg	Arc Angle, Deg	Ply Thickness, in.	Mean Number of Plys	Initial Arc Angle α_0 , Deg
A	45	5	0.0125	99.2	4.64
B	0	10	0.0125	194.4	9.12
C	45	10	0.0125	189.0	8.68

The same laminate material properties were used for all carbon/carbon cylinders. These nine elastic constants were:

$$E_{11} = 2.8 \times 10^6 \text{ psi} \quad G_{12} = 0.63 \times 10^6 \text{ psi} \quad v_{12} = 0.065$$

$$E_{22} = 1.7 \times 10^6 \text{ psi} \quad G_{23} = 0.60 \times 10^6 \text{ psi} \quad v_{13} = 0.290$$

$$E_{33} = 0.75 \times 10^6 \text{ psi} \quad G_{13} = 0.76 \times 10^6 \text{ psi} \quad v_{13} = 0.185$$

where subscripts "1", "2", "3" refer to the warp, fill, and crossply directions, respectively. For each specimen, a set of unit solutions, consisting of a 10,000 lbf axial load, a 10,000 in.-lbf torque and a 100 psi internal pressure was obtained. These unit solutions are summarized in Table 11. Table 12 shows the comparisons between the averaged strain values measured during the tests and the strain values predicted by the AFML computer code.

A summary of the Z and θ calculated and measured strains for the carbon/carbon material is presented in Tables 13 through 15. The data shown are for strain at failure, and agreement is not always good between predicted and measured for those loads in the 45 degree helix cylinders. Agreement is better at the intermediate loads, less than 75 percent of the ultimate, as shown in Table 12.

At the intermediate loads, the comparison of Z strains was very satisfactory for the tension loading. Only one measured versus predicted strain comparison varied as much as 15 percent. All others were less than 10 percent with three values less than 1 percent variation. The hoop and 45 degree strains for the tension loads were also very good. One 45 degree strain varied as much as 50 percent. This was for the 5 degree arc 45 degree helix cylinder. The effects of ± 5 degree helix variation on the sensitivity of a 45 degree helix cylinder is discussed below and provides an indication of a possible cause of the large differences between measured and predicted strain values at 45 degrees.

The Z compression strains were also in satisfactory agreement for the intermediate loads. One of the 10 degree arc 45 degree helix cylinders produced a measured strain 20 percent below predicted. The same test load on another 10 degree arc 45 degree helix cylinder produced a 10 percent variation, with the predicted higher than the measured value. As for the axial tension load, one of the 45 degree measured strains for the axial compression was approximately 50 percent greater than predicted. The remainder of the measured versus predicted strains for the 45 degree helix cylinders varied from 10 to 30 percent. The predicted versus measured for the 45 degree strains with axial compression loading of the 0 degree helix cylinders varied by 2 to 3 percent for two loadings and 30 percent for another loading.

For the combined loading of compression/internal pressure and tension/internal pressure, strains in the Z and 0 directions produced measured versus predicted variations from 0.5 percent to 20 percent, with most variations being less than 10 percent.

The measured maximum strains, 45 degree gages, for torsion testing varied from 5 to 50 percent. Agreement of predicted versus measured for the combined loading of torsion/internal pressure was satisfactory. The measured hoop strain for torsion tests compared favorably to the predicted strains. Variations were from 3 to 24 percent. Measured strains were not consistently above or below predicted strains.

Percentage deviation comparisons for the low strain reading 150 micro-in. or less were not made. The accuracy at low strain readings is questionable.

3. Nonlinear Behavior

The AFML computer code ROSETTE is based on elastic material properties whereas many companies exhibit nonlinear behavior. The type of inelastic

response to applied loads was observed in the test data obtained during this program. Large helix angles, 45 degrees to the load produced nonlinear stress/strain curves for both compression and tension loading. In an effort to improve predictions of strain at failure a simple inelastic analysis using a secant modulus approach was performed for a cylinder loaded in compression. The results of this analysis are discussed below.

The cylinder selected for analysis, 1153769-1-101A, has a 5 degree arc and a 45 degree helix angle. The load condition analyzed was a compression failure. The ultimate load at which this cylinder failed was 32,400 obf axial compression, or 3,850 psi in the cylinder wall. Table 16 shows the axial strain reading versus percent of ultimate load. Strain reading were obtained up to 93 percent of ultimate load. The rather large variance in the 2 strain gage readings above 50 percent of ultimate was characteristic of the 45 degree helix cylinder.

The approach taken was to make an initial baseline run using the linear material properties. The values of stress predicted were then used to intersect the appropriate stress/strain curve and a new estimate of the material constant was made. These revised material constants were then used to make a new prediction. The set of initial material constants used are described below and were based on flat laminate test:

$$\begin{array}{lll} E_{11} = 2.80 \times 10^6 \text{ psi} & v_{12} = 0.065 & G_{12} = 0.63 \times 10^6 \text{ psi} \\ E_{22} = 1.70 \times 10^6 \text{ psi} & v_{13} = 0.185 & G_{13} = 0.760 \times 10^6 \text{ psi} \\ E_{33} = 0.75 \times 10^6 \text{ psi} & v_{23} = 0.29 & G_{23} = 0.60 \times 10^6 \text{ psi} \end{array}$$

where:

1 = warp, 2 = fill and 3 = cross-ply directions

The following stress/strain curves were used for the nonlinear analysis:

<u>Description</u>	<u>Figure</u>
σ_W vs. ϵ_W ~ compression	47
σ_F vs. ϵ_F ~ compression	48
σ_{XP} vs. ϵ ~ compression	49
σ_W vs. ν_{WF}	50
σ_W vs. ν_{W-N}	51
ϵ_F vs. ν_{W-N}	52
τ_{W-F} vs. γ_{W-F} ~ warp axial	53
τ_{W-N} vs. γ_{W-N} ~ rail shear	54
τ_{F-N} vs. γ_{F-N} ~ rail shear	55

where subscripts W, F, and N refer to the warp, fill and cross-ply directions respectively, and the Poisson's ratio, ν_{ij} , is defined as the strain in the "j" direction caused by a load in the "i" direction.

The measured strains at failure, projected from the measured strains at 93 percent of ultimate, for the 5° arc/45° helix cylinder were:

$$\epsilon_Z = -5680 \mu\text{in./in.}$$

$$\epsilon_\theta = +2000 \mu\text{in./in.}$$

$$\epsilon_{45^\circ} = 2600 \mu\text{in./in.}$$

The initial elastic analysis predictions using the linear properties yielded the following results:

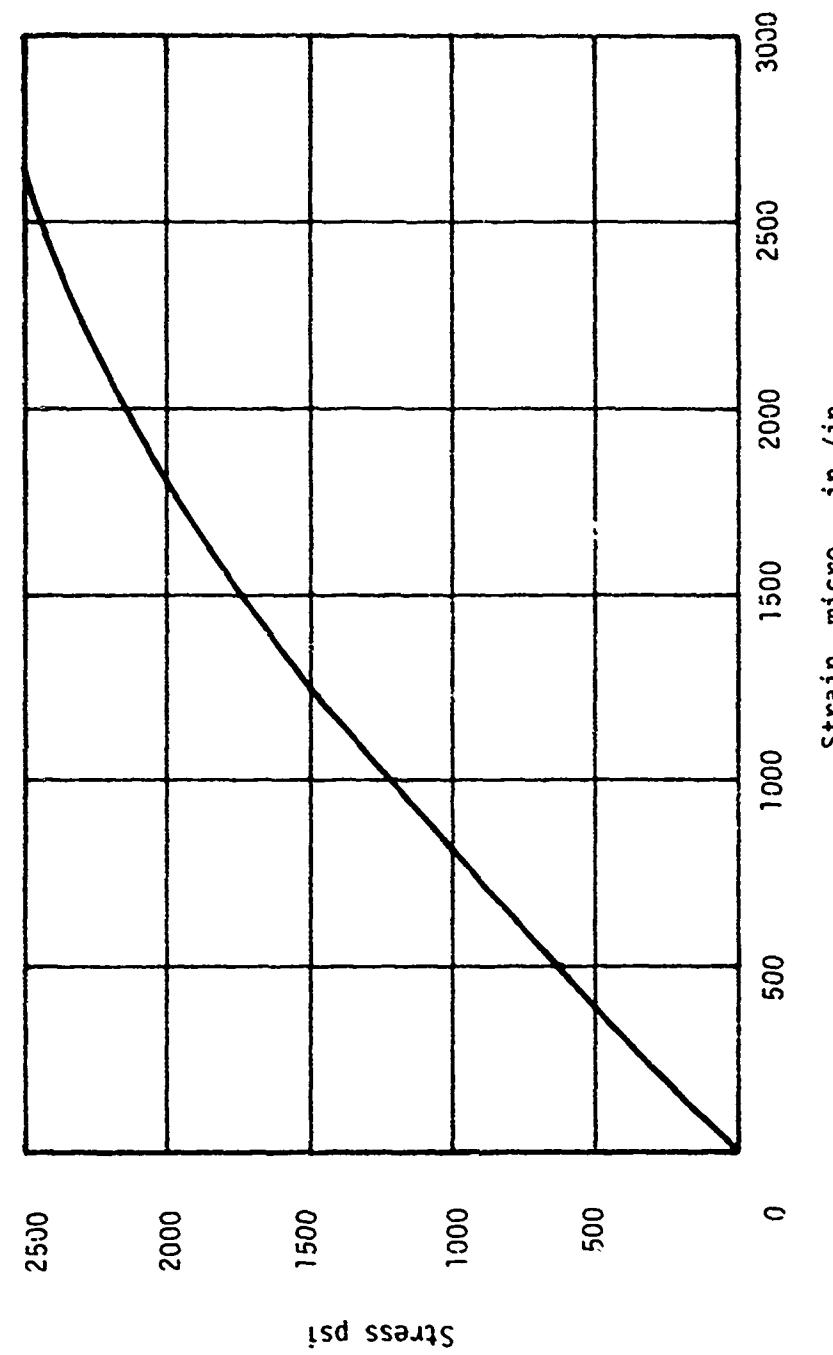

Figure 54. Typical Stress/Strain for Carbon/Carbon Interlaminar Shear
(Rail Shear) loading -Warp Direction G₁₃

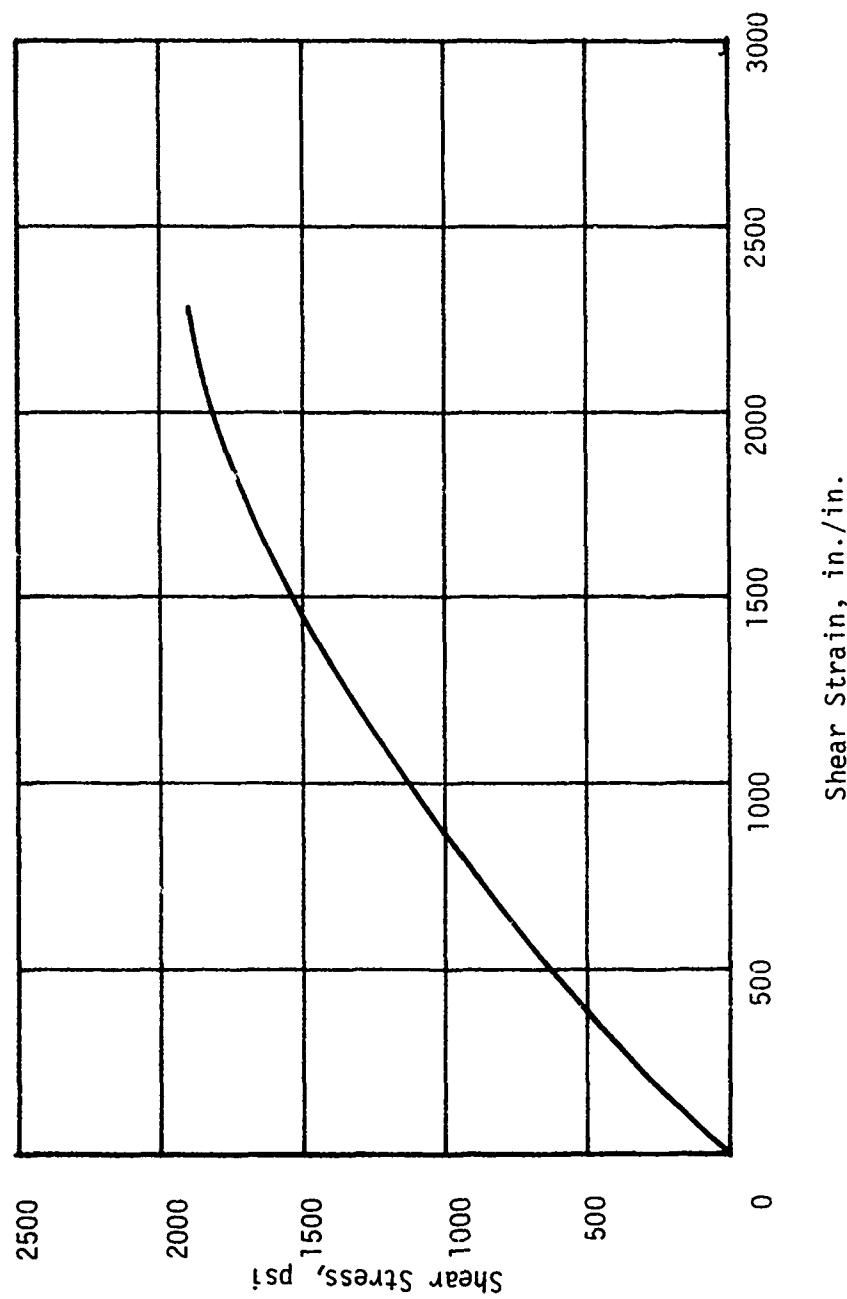

Figure 55. Typical Stress/Strain for Carbon/Carbon Interlaminar Shear
(Rail Shear) Loading - Fill Direction - G₂₃

$$\begin{array}{ll} \sigma_W = -3847 \text{ psi} & \tau_{LT} = 3859 \text{ psi} \\ \sigma_F = -3951 \text{ psi} & \tau_{LN} = 0.70 \text{ psi} \\ \sigma_{XP} \approx 0 & \tau_{TN} = 5.00 \text{ psi} \end{array}$$

Typical stress/strain curves for the nine material constants are shown in Figures 47 through 55. The inspection of these figures indicates that only the material constant G_{12} , Figure 53, requires correction based on the values of stress. All other stress values are still in the initial portion of the material constant curves. From Figure 53, the G_{12} stress/strain curve shows that an τ_{LT} is approximately $8850\mu/\text{in}$. The new G_{12} and the following results obtained as iteration number one.

$$\begin{array}{ll} \sigma_W = -3938 \text{ psi} & \tau_{LT} = 3835 \text{ psi} \\ \sigma_F = -4009 \text{ psi} & \tau_{LN} = 5.6 \text{ psi} \\ \sigma_{XP} \approx 0 & \tau_{TN} = 9.5 \text{ psi} \end{array}$$

Again, the only material constant falling outside the linear range was G_{12} (Figure 53). However, the difference between the initial solution ($\tau_{LT} = -3895$ psi) and the first iteration ($\tau_{LT} = -3935$ psi) does not result in a significant change in G_{12} based on Figure 53. Therefore, an attempt was made to use the predicted strains rather than stresses to obtain a better shear modulus value. The initial run yielded the following values for strain:

$$\begin{aligned} \epsilon_Z &= -5195 \mu\text{in./in.} \\ \epsilon_\theta &= +1597 \mu\text{in./in.} \\ \gamma_{Z\theta} &= 949 \mu\text{in./in.} \end{aligned}$$

From this the maximum strain is computed as:

$$\gamma_{\max} = 6858 \mu\text{in./in.}$$

which from Figure 53 corresponds to a shear modulus of

$$G_{12} = 448,000 \text{ psi}$$

Using this value of G_{12} for the revised iteration number one, yielded the following predictions:

$$\epsilon_z = -6105 \mu\text{in./in.}$$

$$\epsilon_\theta = +2445 \mu\text{in./in.}$$

$$\gamma_{20} = 950 \mu\text{in./in.}$$

$$\gamma_{\max} = 8603 \mu\text{in./in.}, \tau_{LT} = 3837 \text{ psi}$$

from which:

$$G_{12} = 446,000 \text{ psi},$$

or approximately the input, and approximately the same result obtained from using the predicted stress values. The comparison of measured to predicted results is shown below:

Iteration Number	G_{12} (psi)	STRAINS ~ $\mu\text{in./in.}$			
		Predicted	Measured	ϵ_z	ϵ_θ
0	568,000	-5195	+1597	-5690	+2000
1	448,000	-6105	+2445	-5690	+2000

These results show that the initial value used for G_{12} was too high, thus under-predicting the actual values while the attempt to force G_{12} to be on the stress/strain curve at the higher load levels resulted in values of strain too large. However, the use of the non-linear G_{12} improved the predictions and, in fact, made them conservative for both the Z and 0 strains.

As discussed in Section III. E, the measured strain values at failure show significantly more variation than at one third or one half the failing load; therefore, the one data point obtained at failure cannot be assumed to be exact. This limited attempt at a non-linear analysis does not represent a sufficient sample size of the material properties and their normal variabilities to provide a valid test of the nonlinear analysis technique. An increase in the cylinder properties data base at failure is needed to validate any nonlinear analyses at failing loads.

This is shown as an example. Other configurations and loads would involve other nonlinear properties.

TABLE 16. STRAIN GAGE READING VS PERCENT OF ULTIMATE LOAD

92.6	-4339	-4183	-6608	-5377

4. Prediction of Cylinder Failure

This section discusses the methods used to predict various failures in both the carbon/carbon and graphite/epoxy test cylinders. For each of the three helix/arc angle combinations, a carbon/carbon cylinder was failed in tension, compression, internal pressure, and clockwise and counterclockwise torsion. For the graphite/epoxy, two cylinders were failed in compression only.

The same set of unit solutions were used to predict the cylinder failure as to predict its elastic response, only now the stress values were used to predict whether or not failure had occurred. One failure criterion was employed, maximum stress theory. The maximum stress theory simply states that the stresses in the principal material directions must be less than the respective laminate strengths. Otherwise, failure is assumed to have occurred. This theory is actually three subcriteria and does not account for any interaction between modes of failure in a specimen.

a. Graphite/Epoxy Cylinders

The ultimate strengths for the graphite/epoxy material are summarized below:

<u>Strength Component</u>	<u>Ultimate Stress, psi</u>
Fill-Tension	41,500
Fill-Compression	73,000
Warp-Tension	190,000
Warp-Compression	140,000
Warp/Fill Shear	17,200

For the graphite/epoxy cylinder, only two were tested to failure, both in compression. No other failure tests were run of the graphite/epoxy cylinders. The results of these two compression failure tests are shown in Table 17. Similar to the carbon/carbon failure data, Table 18, margins of safety are calculated for each stress in the principal material directions. As can be seen

TABLE 17. AEROJET 3431 GRAPHITE/EPOXY CYLINDERS COMPARISON OF MEASURED VERSUS PREDICTED FAILURE (ALL STRESSES ARE LBS PER SQ IN. PSI) (2)

(1) Negative values indicate failure

from Table 17 the predictions were very unconservative in that they showed positive margins of safety at the test failure load. The most likely failure mode, based on the analysis, is warp-fill shear. The agreement was not satisfactory for the graphite/epoxy. Failure loads were lower than anticipated because of possible buckling and the low fiber volume. Therefore, the analysis was not continued.

b. Carbon/Carbon Cylinders

The ultimate stresses and strains for the carbon/carbon materials are summarized below. All values shown are averaged values.

<u>Strength Component</u>	<u>Ultimate Stress, psi</u>	<u>Ultimate Strain, 10^{-6} in./in.</u>
Fill-Tension	5,670	3,900
Fill-Compression	6,333	4,983
Warp-Tension	9,951	3,915
Warp-Compression	13,727	5,758
Warp/Fill Shear	3,487	7,305

Table 19 shows the measured and predicted stress levels for the carbon/carbon material at failure for each cylinder configuration for each type of failure. Stresses shown are in the plane of the laminate (warp-fill plane) at the outer radius of the cylinder. Analysis showed that maximum stresses do not always occur at the outer surfaces. However, measurements were taken on the outer surfaces, and warp, fill, and warp-fill shear stresses are shown and each is compared with the allowable values shown above, and a margin of safety (M.S.) is computed. If the margin of safety is less than or equal to zero, failure is predicted. Table 18 shows a considerable variation of the accuracy of the failure predictions. For example, for Cylinder C, in the tension test, the predicted failure was at 97 percent of the actual ultimate load whereas, in the compression test, the maximum stress theory predicted

failure at 91 percent of ultimate. Within a given test type, the accuracy of the prediction varied with the cylinder layup. For example, in the counter-clockwise torsion test, the predicted load at failure, based on a maximum stress theory, was 108 percent of ultimate for the fill fiber in Cylinder A, 141 percent of ultimate for Cylinder C, and 80 percent of ultimate warp-fill shear for Cylinder B. The worst agreement was for the internal pressurization test and for Cylinder B, while the best agreement for all tests was obtained on Cylinder C.

In those cases where any criteria indicated failure at a level lower than the actual, the predictions were interpolated to indicate what the predicted value would be at failure. The values are noted in Table 18 below the 10 percent load prediction.

5. Sensitivity Studies for a C-C Cylinder

Sensitivity studies were limited; however, some sensitivity studies were made to show effects of elastic constant variation and helix angle variation. The variations selected for evaluation were ± 20 percent for the elastic constants and ± 5 degrees for the helix angle.

The number of cylinders tested to failure was limited to one for each type of uniaxial load. The comparison of measured versus predicted values used elastic constants based on the averages from laminate and tube tests. Furthermore, these average values were generally obtained from stress values; therefore, statistical range of property variation could not be ascertained with any confidence. An arbitrary range of ± 20 percent was selected to determine effects of variation about the average for all nine material constants.

The results compared with the nominal prediction of stress in the warp and fill yarn of the 5 degree arc 45 degree helix cylinder

are shown in Table 19. Also shown are the nominal shear stress warp-fill (W-F) and the interlaminar shear at the measured failing load of 32,000 lb.

The variation in warp fiber compressive stress at the load of 32,000 lb. for a +20 percent E_{11} , E_{22} , or E_{33} is rather small. Maximum variation in warp fiber stress is +92 psi for a 20 percent reduction in E_{22} and -61 psi for a 20 percent increase in E_{22} . Similar results, although with less variation, were obtained for the fill stress with \pm 20 percent change in E_{22} and E_{11} . The \pm 20 percent change in E_{33} produced no change in warp or fill fiber stress. Changes in warp-fill shear and interlaminar shear stresses were insignificant for the \pm 20 percent change in E_{11} , E_{22} , and E_{33} .

The \pm 20 percent variation of v_{12} , v_{13} , and v_{23} produced less than 20 psi change in warp and fill compressive stress. The warp-fill shear stress and interlaminar shear had even less variation for the \pm 20 percent variation in Poisson's ratio. G_{12} was the only shear modulus which showed any effect on warp or fill compressive stress from the \pm 20 percent variation. Changes were small, less than 100 psi. Variation in G_{12} also produced very small changes in warp-fill shear stress and interlaminar shear stress.

From these determinations, it appears that the computed stress of the 5 degree arc 45 degree helix is rather insensitive to \pm 20 percent change in any of the elastic constants. The G_{12} at -20 percent of the obtained average reduced the warp-fill shear stress from -3837 to -3820 psi. Although the warp-fill shear stress is the most likely failure mode, the 17 psi decrease in stress is less than 1 percent of the total warp-fill stress. It would be difficult to isolate any effects on ultimate compressive strength of the cylinder from this small change.

It is believed that results similar to those shown in Table 19 would be obtained for tensile testing of the 5 degree arc 45 degree helix cylinder and also for both compression and tension testing of the 10 degree arc 45 degree helix cylinder.

The sensitivity of model predictions of fiber compressive stress, warp-fill shear stress, and interlaminar shear stress is more for a ± 10 percent change in helix angle than for the ± 20 percent change in elastic constants. The stress values for the fiber stress in the warp and fill direction are shown in Table 20. The +5 degree helix angle change produces approximately 600 psi decrease in warp fiber stress and the -5 degree helix angle change produces approximately 600 psi increase in warp fiber stress. Similar results were obtained for the predicted fill fiber stress.

The warp-fill fiber shear stress and interlaminar shear stress are affected much less by the +5 degree helix change as shown in Table 20.

As discussed in Section III, D2, closer control than ± 5 degree helix angle on the fill yarns is not likely feasible using current fabric conversion, prepeg, and lay-up processing procedures. As the warp-fill fiber shear stress approaches the allowable stress level, control of the helix angle effects becomes significant.

Current designs using graphite/epoxy and C-C material should take into account the effects of this degree of non-uniformity.

Some empirical verification of this predicted phenomenon is needed, particularly at the 45 ± 5 degree helix angle and also at the 15 ± 5 degree helix angle, as this might be a steeper part of the curve for both materials. Furthermore, the current trend in fabrication of exit cones

has been toward complicated ply pattern with a significant change (45 degree) in helix angle ID to OD. Techniques for analyzing these effects are needed.

Work is in progress by AFML and PDA to extend this work to involute exit cones that will aid in the analysis of the changing helix angle for the more complicated ply patterns.

SECTION IV

CONCLUSIONS

Notwithstanding variability of individual solutions, the AFML involute computer code was verified as a useful tool for predicting behavior of involute composite cylinders under uniaxial and combined loads using linear elastic laminate properties. Specific differences in the predicted versus measured strains were as high as 100 percent; however, the general variability was less than ± 10 percent.

Development of photomicrograph standards appears to be feasible for both test panel and tag-end samples.

A tentative but promising non-linear analysis has been presented.

The thin wall tubes were not satisfactory for obtaining ultimate compressive strengths. Values obtained were from 30 to 40 percent lower than the laminate for both graphite/epoxy and carbon/carbon tubes loaded parallel to warp fibers.

The program test matrix did not provide empirically supported sensitivity studies; however, limited analytical studies indicate warp and fill fiber stress, warp-fill shear stress, and interlaminar shear stress are sensitive to ± 5 degree variation in the 45 degree helix angle.

A ± 20 percent variation in material elastic constants makes relatively small (less than 3 percent) differences in the predicted warp or fill fiber stress, warp-fill shear, and interlaminar shear stress for compression loading of a 45 degree helix cylinder.

Prediction of cylinder behavior from laminate properties requires the following:

1. Warp and fill alignment be within ± 5 degrees or better.
2. Load be transmitted uniformly into the specimen.
3. Preloading and checkout to assure uniform loading for the cylinders. (Less than 10 percent variation for initial loading was achieved; however, some variation at failure was greater than 10 percent.)
4. Laminate and cylinder material should have the following:
 - a. Same density
 - b. Ply thickness
 - c. Fiber volume factor
 - d. Matrix condition

The cylinder test length was questionable for the internal pressure loading and required sensitive alignment of pins to prevent non-uniform strain in compression and tension loading.

SECTION V

RECOMMENDATIONS

Additional sensitivity evaluation should be conducted. All types of loading and variation of elastic constants and currently used arc and helix angles should be analyzed with empirical validation of selected parameters.

Further evaluation of the use of photomicrographs is recommended as a technique to assure reproducibility for both in-processing steps and the final processing for carbon/carbon materials.

The increase of cylinder length should be considered for any subsequent cylinder testing where loading is introduced by shear pins in the cylinder wall. This would reduce or eliminate effects of misalignment caused by pin/hole mismatch.

Further examination for non-linear behavior similar to that reported herein should be conducted to verify the applicability of the AFML involute computer code at involute structures experience in solid rocket applications.

Additional analysis and methods of treatment for the non-linear behavior of involutes, particularly with high arc and helix angles, should be conducted for all types of loading.

The program for cylinders should be expanded and continued to include combined loading to failure of involute cylinders.

APPENDIX

TEST SPECIFICATION CONFIGURATION

The uniaxial test specimens, tube, cylinder configuration and an example of a cutting plan are contained in this section. The same specimen design was used for the graphite/epoxy and carbon/carbon material. In some instances thickness was reduced for the stronger and stiffer graphite/epoxy material.

A. CUTTING PLAN

The cutting plan for the 6 by 3 by 3 in. laminates is shown in Figure A-1. The plan shown is for warp yarns in the 6 in. direction. Similar plans were used for the fill direction and the 0.250 in. laminates.

B. LAMINATE AND TUBE UNIAXIAL TEST SPECIMENS

The tensile specimen is shown in Figure A-2. The specimen is a standard dog-bone shape and is 9 in. in length. The ends are tab with glass/epoxy for testing.

The compression specimen is also shown in Figure A-2, and is dog-bone in shape. It is 6 in. shorter with a reduced tab and section, which is mounted into the compression test fixture. This specimen produced good results for both graphite/epoxy and carbon/carbon laminates.

The crossply tensile specimen, Figure A-3, is 3 in. in length and is subsequently bond into end supports for attaching in the test machine. Alignment into these supports is very critical toward obtaining good crossply tensile results. A modification of this specimen was also used. A straight section of 0.5 by 0.5 by 3.0 in. was bonded into the end supports. Results were good, and the specimen machining losses were eliminated.

The crossply compression specimen is not shown. The standard ASTM D695, D3410 (AFML TR-67-332) was used. Crossply compression was not obtained for the graphite/epoxy.

The rail shear specimen is shown in Figure A-4. The specimen was designed in accordance with AFML-TR-69-311. The specimen was used to test shear and measure shear modulus in the G_{13} and G_{23} direction for both the graphite/epoxy and the carbon/carbon materials.

The notched shear specimen is shown in Figure A-7. The standard ASTM-D2345 specimen was used. The specimen and test procedure are also shown in AFML-TR-332, Supplement I, Structural Plastics Application Handbook. Both the graphite/epoxy and carbon/carbon materials were tested with warp and fill parallel to the load direction. Supports were used to reduce bending.

The tube specimen, shown in Figure A-8 was the same for both of the materials. The specimen was satisfactory for the torsion test and fill compression testing of the carbon/carbon. It was not satisfactory for ultimate compression strength of the graphite/epoxy or the warp strength of the carbon/carbon. The specimen was used as the source for G_{12} and G_{21} shear moduli. Poisson's ratio ν_{12} and ν_{21} were also determined from compression loading of the tube.

C. CYLINDER SPECIMENS

The cylinder test specimens for the graphite/epoxy and carbon/carbon materials are shown in Figures A-7 and A-10, respectively. The only difference between the two specimens is the test section wall thickness. The graphite/epoxy has a nominal wall thickness of 0.074 in. The carbon/carbon wall was made thicker, nominal 0.295 in.
